In the case of measles we have an explanation of the comparatively large number of secondary cases. The disease is a mild one, speaking comparatively, and many cases are not properly isolated in the homes of the poor; consequently, rooms and materials are infected outside of the apartment in which the patient belongs, and which the disinfector fumigates. Moreover, during the past two years we have had so many cases of contagious diseases that measles have frequently not received the attention of our inspectors and disinfectors that should have been given it, scarlet fever and diphtheria taking most of the time of the men.

The contagion of diphtheria would, from our statistics, seem to resist the action of sulphur dioxide most, and to be the most difficult to destroy. This is, in my opinion, due to the manner of its infection. The other three diseases infect a room mainly by means of the medium of the air, the contagion being exhaled or given off from the body and deposited evenly over the surfaces exposed to the infected air. In diphtheria, membranes and secretions are also infected, and the contagion is protected by being surrounded by a protecting medium into which sulphur dioxide cannot easily penetrate. This is probably the reason why biological experiments with $SO_2$ are not satisfactory.

It is impossible to imitate in the laboratory nature's method of infection. The power of penetration of $SO_2$ into the culture-mediums cannot be very great. The medium must somewhat protect the culture within it, so that only those cultures are affected that are on the surface of the medium. Just as diphtheritic secretions protect diphtheritic contagion, so do culture-mediums, to a less extent perhaps, protect cultures.

In nature's method of infection the infected air is carried by draughts and air-currents into cracks and corners accessible only to a gas liberated under much the same conditions as the contagion.

*Conclusions.*—It would seem that the proper and most practical method of disinfection of dwellings, after the occurrence in them of exanthemata and of diphtheria, is by means of sulphur dioxide, and that all clothing, bedding, etc., used in direct contact with the patient, should be removed to a disinfecting station, properly equipped, and there subjected to heat of sufficient intensity to destroy all contagious matter. This in future will, I believe, be the method pursued by the Health Department of the City of New York.

ADDENDA.—The above table shows the details of the cases I have given. It will be seen that a large number of the secondary cases occurred three months and over from the beginning of the primary case.

Many of these secondary cases occurred in other apartments in the same house as the primary case, but were probably not due to contagion from it. It is impossible, however, to say that they were not caused by the first case. I have counted them among the cases possibly

In the discussion of this paper by the American Public Health Association the method of fumigation was criticised, it being alleged that not sufficient moisture was present with the sulphur dioxide to insure the best results. A very important point in this connection was brought out. The use of alcohol to ignite the sulphur, as described in the paper, adds materially to the moisture in the air of the infected rooms. The amount of alcohol used is, as I have stated, about four ounces to each charge, say of six pounds. This amount of alcohol will develop fifty quarts of steam, approximately. To Dr. E. H. Bartley, of Brooklyn, I am indebted for this estimation and suggestion.

## RACHITIC PSEUDO-PARAPLEGIA.[1]

BY HENRY W. BERG, M.D.,
NEW YORK.

I AM about to discuss a class of cases which have received but little attention from writers upon rachitis. The bone lesions in this disease are so prominent, and seem to be so essentially the disease, that all other phenomena connected with the condition are overshadowed and far less studied than would be proper from their intrinsic importance. The view that rachitis is a disease of the bones *per se* is no longer maintained. It is certainly recognized to be a disease of the blood, affecting all the structures of the body, with lesions especially located in the osseous tissues; not limited to these, however, but affecting very materially the muscles and fibrous ligaments and tendons. It is not my intention, in this paper, to discuss all the effects of rachitis, but I shall call attention to those cases in which general rickets is accompanied by an inability to use the lower extremities owing to muscular disability. The symptomatology of this class of cases is about as follows: A little patient, from two to four or even five years old, is found to be unable to walk; or, among the younger cases, unable to stand erect, or even sit up. The amount of disability varying with the severity of the case and the youthfulness of the patient. The parents find that at an age when other children are creeping their child makes little or no effort to creep—later on there is no voluntary effort to stand erect; and when the little patient is held erect by the arms, the knees bend under the weight of the body. Voluntary attempts to stand are not made at all, or made only when the patient is long past the age when other children are running about. Other, generally older, cases are found who, although they stand erect when held, or when they support themselves by holding on to surrounding objects, yet do not dare to make the attempt to walk, or if they do attempt to walk they go with their feet and legs spread wide apart, so as to obtain a better basis of support, and with the body bent forward in the effort to maintain their equilibrium. Their

[1] A paper read before the Orthopedic Section of the New York Academy of Medicine, October 18, 1889.

progress is accentuated by frequent stumbles and falls—the little patient walks like a partial paraplegic. In short, we have all grades of muscular disability, varying in degree from total inability to use any of the muscles whose function necessitates the partial or complete erect posture of the body to a slight weakness in standing and walking.

Such is the history obtained from the parents. Examination of the patient shows a typically rachitic body; fontanelles wide open long beyond the age when they should have closed, the bosse on the frontal and temporal bones large and prominent, the other portions of the cranial bones transparent and thin even to the point of craniotabes. The junction of the ribs with the costal cartilages is marked by the so-called rachitic rosary. The joint-ends of the long bones are enlarged, and the abdomen is large with a distinct upper boundary externally, corresponding to the bony insertion of the diaphragm, which, in its rhythmical action, has drawn the ribs inward. The pelvis is flattened posteriorly in those patients who have not yet learned to sit up. The long bones of the leg show little or no deformity, inasmuch as these patients have avoided standing and walking. There is no bow-leg or knock-knee present as a rule. In other words, the deformities due to the use of the lower extremities in the soft stage of the osseous disease are absent. An important diagnostic point, however, is that the bony prominences present at the muscular insertions are felt to be exceedingly tender. Thus there is pain on touching the patella, the external and internal condyles, and the upper portion of the tibia. This excessive tenderness at the points of muscular insertion is due to a great extent to a chronic periostitis, which results in the thickening at the joint-ends to which I have just referred. There is in addition a certain amount of tenderness in the body of the muscles; this is a factor to a greater or lesser extent in all cases of rickets, but is excessive in the paraplegic patients. Pressure of the mass of the limbs, which in other children causes laughter, will here give rise to a cry of pain. These children wish to be let alone. Although many children suffering from general rickets are fat and well-nourished in appearance, with rounded cheeks, soft and flabby muscles, the cases under consideration are, as a rule, pale and thin; the skin excessively white, with the capillary vessels well marked. The muscular tissue has little or no adipose covering, which accounts, I think, for the hypersensitiveness of the muscular nerves of sensation; the skin hangs loose and flabby, and the little patients present all the features of malnutrition, resembling often cases of marasmus, without, however, giving a history of diarrhœa or marked stomach affection.

Although presenting the more or less perfect paraplegia to which I have referred, a careful examination of the patient in the recumbent posture shows that the little one has good control over the various movements of all the joints. Beginning with an examination of the lower extremities we find that as the patient lies upon his back he can flex, adduct, abduct, rotate, and extend the thigh, these movements all being performed by the child in its effort to remove the limb from irritations, such as pinching, pricking with pins, etc., on the part of the examiner. When we hold the little patient's attention and raise the limb we will be able to demonstrate the presence of that partial cataleptoid state common to infancy. Thus in raising (flexing) the hip-joint the contraction of the psoas magnus will retain the limb in the position in which it was placed, for a few seconds. In this way we can demonstrate the fact that every muscle retains its power intact. The motions about the knee- and ankle-joints are perfectly and voluntarily performed, or are shown to be present by the cataleptoid test. On the other hand, while in healthy children, in the recumbent posture the whole leg extended at the knee can be flexed on the pelvis, and retained for some time in the straight position without drooping, these little patients manifestly find difficulty in keeping the extended limb flexed upon the pelvis, for even a short time. Some will not make the effort, others will allow the leg to fall immediately after having straightened it. In other words, they are unable to support the weight of the limb in the elevated position and as a result it falls.

From their inability to stand and walk these patients are supposed by the parents to be paralytic. The physician is consulted, and it becomes of the utmost importance to be able to make a positive differential diagnosis between these cases and the various forms of true paralysis affecting infancy, the more so from the fact that the prognosis in true rachitic pseudo-paralysis is excellent for complete recovery, while that of paraplegia due to lesion of the cord or brain, I need not say to this audience, is in many cases a hopeless one.

I shall be excused, therefore, for dwelling unduly upon the points of difference between paralysis due to organic disease of the nervous system and the functional paralysis of rickets. At the same time the remaining symptomatology of rachitic paralysis, which is chiefly negative, will be brought out without the risk of otherwise unavoidable repetitions.

*Differential Diagnosis.*—The most frequent form of organic paralysis occurring in infancy is poliomyelitis of the anterior horns. Cases of this disease in which the paralysis is paraplegic might possibly be confounded, in rachitic children, with rachitic pseudo-paraplegia. A careful examination will serve to reveal the points of difference. In poliomyelitis the limb is atrophied and surface cold. In rachitis there is neither atrophy nor cold surface; the patient may be thin, and ill-nourished, but the appearance is not in any sense that of general muscular atrophy. Examination of the patient's power in the affected limbs also shows the radical difference that while in infantile paralysis there is real paralysis, so that the patient has lost all power in the affected muscles, in rachitic pseudo-paraplegia there is no paralysis, but only weakness, so that the patient has perfect use of the muscles except when these muscles attempt to perform voluntary motions and support the weight of the body and limb at one and the same time. The patellar reflex while preserved to its normal extent in rickets, is generally diminished in cases of paraplegia due to poliomyelitis. Finally, the battery will serve to differentiate the two affections, the faradic current yielding no response in the muscles affected by infantile paralysis, while in rickets faradic contractility is preserved and normal, so also the galvanic reaction of degeneration so characteristic of all paralysis due to disease of the peripheral motor nerves and anterior gray horns in the spinal cord while present to a marked extent in cases of poliomyelitis of the anterior horns, is absent in cases of rickets, the latter shows the normal reaction, Ca.C.C. > An. C.C., Ca.O.C. < An. O.C., or entirely absent. These points of difference will readily serve to distinguish cases of infantile paralysis from the pseudo-paralysis of rickets.

Not so readily distinguished, however, are recent cases of post diphtheritic paralysis, and paralysis following cerebro-spinal meningitis. In the former, recovery is the rule, because the lesion of the nervous centres is a temporary one. Hence the reactions of degeneration and atrophic appearances are absent; furthermore, the paralysis, while affecting both lower extremities and back, is frequently partial and does not completely paralyze all motion in the affected extremities and back. Thus the disability, like that in rachitic paraplegia, is most marked when the muscles are exerted in such a position that they are compelled to support weight and perform motion at the same time. The diagnosis will rest to a great extent upon the history of the case, recent origin of the paralysis, the preceding occurrence of diphtheria, above all the involvement of the muscles of the naso-pharyngeal and laryngeal region, resulting in difficulty in swallowing and speaking, an examination of the faucial arches showing paralysis of the anterior portions of the fauces, and diminution of the patellar reflex. All of these points will generally serve to distinguish the two affections. So

also in temporary paralysis following cerebro-spinal meningitis, the history of the case, together with the presence of real paralysis affecting the cranial nerves, will serve as diagnostic features, while cases in which the lesions of the nervous system have become permanent will resemble those suffering from hemiplegia and paraplegia due to cranial disease, with which rachitic pseudo-paralysis can scarcely be confounded. Cases of tetanoid paraplegia or spastic paralysis do not resemble rachitic pseudo-paralysis in any respect, except that in both the paralysis is not really a paralysis. Mild cases of spastic paralysis might lead to a question as to diagnosis, but the increased patellar reflex, the exalted muscular activity, apparently beyond the control of the patient, frequently, retarded mental development as an accompaniment of the similar condition of the motor areas in the brain, will differentiate these cases from those of rachitic pseudo-paralysis. Cases in the early stage of the paraplegia occurring in the course of Pott's disease, when the paralysis is due to the pressure of meningeal exudation products upon the anterior portion of the spinal cord, rather than to an organic affection of the cord itself, might readily be confused with this affection, particularly if the kyphosis, being but slight, had not been noticed. Here the paralysis might develop very slowly, and would be but partial. The rachitic curvature of the spine might help to confuse the diagnostician. A careful examination of the spine will reveal the Pott's disease of the lower dorsal vertebræ. The symptoms of vertebral disease in this region, such as psoas contraction and psoas abscess, also, occasionally, paralysis or weakness of the bladder accompanying the paralysis of the lower extremities, all of these, will aid in arriving at a proper diagnosis.

The pathology of this condition is the pathology of rickets. The rachitic dyscrasia is the cause of the muscular weakness in rachitic pseudo-paralysis. We must not forget, however, that in rickets there have been observed, by very reliable observers, cases in which paralysis, evidently of cerebral origin and generally hemiplegic in distribution existed. Post-mortem findings, however, in these cases showed the lateral ventricles filled with fluid, and the cerebral convolutions, about the motor area particularly, flattened and compressed, so that these are really cases of hydrocephalus accompanying rachitis. It is uncertain, however, whether such a condition is to be considered a complication or an effect of the rachitic disease of the blood. Under no circumstances are they at all comparable to the cases of idiopathic paralysis which we are considering.

It becomes a subject for inquiry as to the pathogenetic connection between the rachitic disease and the pseudo-paralysis which we have described. To understand this we must consider the mechanics of muscular activity. When by the contraction of its muscles a limb is set in motion and made to perform work, the sum total of the work performed consists of the following elements. 1. Counteracting the weight of the limb to be moved. 2. Imparting to the limb or member the force necessary to perform activity. The sum of the two is the amount of muscular work. It is evident that in standing quietly the entire amount of work is spent in maintaining the stiffness of the joints, and counteracting their tendency to yield under the superincumbent weight of the body and limbs, while in walking more work is performed, the body being supported and carried, at the expense of friction and other impediments, over space. Both of these things simultaneously the muscular tissue, weakened by the imperfect nutrition of the rachitic blood, is unable to perform in some cases; in others, while the utmost force exerted suffices to support the body in the erect posture there is not sufficient strength to carry that body over the ground. If, however, the weight of the body is supported by some other means, such as the hands of an assistant, then the movements of walking are frequently very well and even firmly performed.

This explains why these patients can move their limbs in every conceivable direction while in the recumbent posture. Here they support only the weight of the limb, and not of the whole body. So also these patients can use the upper extremities, although it will be found that when they attempt to lift weights such as other children can readily raise they fail lamentably.

This disability is furthermore increased by the flaccidity of the ligaments, the softness of the bones or levers by which the muscles act, and the rachitic periostitis present, particularly at the points of muscular insertion. It is to this periostitis, I think, that much of the thickening at these points is due, and also the tenderness to which I have already referred. Finally, the pain in the muscular tissue is also an important element in the disability of these cases. While pain is present with every motion the little patients instinctively prefer to keep quiet.

*Prognosis.*—It is a gratifying fact that the treatment of these cases is uniformly successful, and where an improper diagnosis has been made, often very brilliant. These are the cases that give such good results after circumcision, not owing to any virtue in that operation, as far as the rachitis is concerned, but because they uniformly get well. Indeed, to recognize the nature of the disability is of far more importance than the treatment.

One of my own cases, treated at the Orthopædic Dispensary some three years ago, may be interesting in this connection. John S——, two years and eight months of age at the time of application at the dispensary, which was September 23, 1885. At that time he suffered from what the examining surgeon considered atrophy of both lower extremities, which, however, appeared to me to be the wasting of malnutrition and disuse. Patellar reflex normal, or slightly exaggerated; contracted prepuce. While under examination by the examining surgeon, there seemed to be some rigidity of the adductors of the leg and the muscles about the knee-joint. The patient was said by the parents never to have stood alone, and certainly he had never made any attempt to walk. The boy was therefore referred to the neurological class, which was then under my care, with the diagnosis of "slight spastic paralysis" upon his card. On examination I found him typically rachitic, large forehead, fontanelles not yet closed, features delicate, skin abnormally white, veins marked; absolutely unable to stand or walk, spine slightly curved, patellar reflex slightly more marked than usual. Spastic condition of the adductors above referred to evidently owing to fear—patient fearing the application of force in stretching the prepuce, a former examination by an eminent Albany surgeon having pained him very much. This surgeon had advised circumcision as the only mode of curing the paralysis, which he considered the reflex result of the long and contracted prepuce. I made a tentative diagnosis of rachitis with pseudo-paraplegia, put the boy under massage by the parents at home, electricity, and anti-rachitic diet.

In addition phosphorus was given alternately with iron. In less than six weeks the patient was able to walk, and on November 17, 1885, I find the note in dispensary records that the patient walks very well, although awkwardly. He was discharged perfectly cured in the spring of the following year.

Such will be the result of proper treatment in all cases of rachitic pseudo-paraplegia. And frequently these cases would get well in spite of any form of treatment.

Treatment of this condition should be directed locally to the weakened muscles, and generally to the system at large to counteract the effect of the rachitic malnutrition. I consider the latter indication more important than the former. Remove or improve fault of nutrition and muscles will gain strength sufficient to perform their physiological work. A proper diet is, of course, of the utmost importance. This I consider to be that form of diet which will be most readily digested by these patients,

without regard as to whether the articles of food are rich in phosphates or not. These children should have a great deal of milk—no tea and no coffee. Cocoa, made very thin, is desirable once a day. They should eat lean meat not oftener than once a day, plenty of beef-broth, all of the lighter cereals, and small quantities of the lighter fruits. Nothing that is indigestible and which experience has shown to be indigestible in any given case should be given. Cod-liver oil, if digested, will do good in small doses; it should not, however, be given in emulsion with the hypophosphites, for these salts are not only utterly inert, as I shall show, but being frequently mixed with syrups are apt to interfere with the digestion of the oil. As to medicines, we have in rachitis one of the diseases for which experimental physiology has given us a remedy. I consider that one of the most positive facts in therapeutics is the beneficial effect of phosphorus in the cure of rickets. I make this assertion on the strength of Wegner's investigations. He fed young and growing animals (rabbits and fowls) particularly, with small, non-poisonous and easily assimilated doses of finely-divided phosphorus during periods of many months, and arrived at positive conclusions.

He found that in these animals thus fed, those portions of the long bones in which the original cartilage becomes ossified into cancellous tissue underwent a firmer form of ossification than in animals that had not received the phosphorus. In the former, instead of cancellous tissue, spongy and filled with marrow, firm and compact bony substance, like that formed on the outside of the long bones, is found. But the cancellous tissue formed before the administration of the phosphorus remains unchanged at first; in animals killed later on this cancellous tissue is found be absorbed to form the medullary canal. The bone formed under the influence of the phosphorus diet was found to be well-formed bone. The microscope showing not the large marrow-spaces of ordinary cancellous tissue, but spaces contracted to the size of the Haversian canals in compact bone-tissue, and the cartilage-cells converted not into marrow-cells, but into bone-corpuscles surrounded by the proper amount of intercellular substance. If the phosphorus diet is continued the whole of the cancellous structure is converted into compact bone-tissue. Even the portion of the bone developed from the periosteum, ordinarily hard and compact, was found by the microscope, in phosphorus-fed animals, to have become finer in structure, with the Haversian canals smaller though never entirely obliterated. Even in older fowls fed on phosphorus for a long time, the bones were found to have the cancellous structure entirely absorbed, and replaced by compact tissue, while the medullary canal was entirely filled by compact bony tissue, so that the bones were no longer tubular, but compact bony masses. The chemical composition of bone in animals fed on phosphorus for a long time was found to be unchanged, there being neither more nor less phosphorus than should be present in the normal composition of bone. Wegner furthermore showed that animals thus fed on non-poisonous quantities of phosphorus increased in general size and strength, the *muscles particularly*, as well as the bones of the body, becoming stronger. I do not think that there is any other remedy in the whole range of therapeutics for which experimental physiology has borne so strong a testimony. I have, accordingly, since reading Wegner's investigations some five years ago, been accustomed to give phosphorus as a nerve-tonic, and above all, as a specific for rickets in children. So great an authority as Dr. A. Jacobi, in this city, I have heard speak in the most enthusiastic way about the action of phosphorus in the latter condition. I do not give the phosphorus with oil, but prefer, and have always had satisfactory results from the use of Thompson's Solution. This, as you know, is a solution containing $\frac{1}{100}$ grain to the drachm. I find that the mixture made by Hazard, Hazard & Co., although not in all respects like the original formula, is a very good one, the odor of phosphorus being entirely absent.

The formula used by this firm is as follows:

| | |
|---|---|
| ℞. Phosphori | gr. j. |
| Alcohol. absolut. | ♏ cccl. |
| Spt. menth. pip. | ♏ x. |
| Glycerinæ | ʒ ij. |

M. and Sig.

Of this mixture I give to a child, two to four years of age, six minims t.i.d., to be increased one drop weekly until ten drops are given, larger doses I do not think necessary. For younger patients correspondingly smaller doses will be best.

Other tonics, such as iron, small doses of nux vomica, etc., are indicated in the anæmia accompanying the rachitis.

As to the local treatment it consists chiefly of massage and electricity. Massage should include passive movements of the joints and kneading and rubbing the various individual muscles, remembering, however, the hypersensitiveness of these patients, and accommodating the severity of the treatment to it.

The most valuable agent locally to the weakened muscles and limbs is undoubtedly electricity. It acts by setting the muscular fibres into contraction without putting the strain of voluntary muscular effort upon them. Furthermore the electric current acts as a mild rubefacient and general stimulant to the nerves and muscles. For the purpose of muscular contraction, I use the faradic current no stronger, however, than is necessary to throw each of the muscles into contraction. The principal muscles should be selected for individual treatment and caused to contract a few times under the influence of the current. As a general stimulant galvanism is indicated and should be used on alternate days with the faradic current. I generally apply a descending current, placing the positive pole on the spinal column at the mid-dorsal region, while the negative pole is passed up and down the extremities. Applications should not exceed five minutes in duration for each limb.

245 Seventh Street.

## REPORT OF A CASE OF CONGENITAL DISLOCATION AT THE HIP.

By JOHN RIDLON, M.D.,

Assistant Surgeon at the Vanderbilt Clinic, New York.

D. K——, female, aged ten and one-half years, came under observation February 16, 1888. She is the eldest of two children of healthy parents. When she began to walk, at fourteen months, she limped, and it was noticed that the right leg was shorter than the left. No cause could be assigned; she had never hurt herself sufficiently to cry. Nothing had been done in the way of treatment; and she was brought for advice about a high shoe.

*Examination.*—She walks with a very decided limp; the right leg is rotated outward; the thigh is flexed on the pelvis, and the lumbar spine is lordosed. It requires a blocking under the foot of three inches to enable her to stand fairly erect. (See Figs. 1, 2, and 3 next page.)

From anterior superior iliac spine to inner malleolus, right, 26½ inches; from anterior superior iliac spine to inner malleolus, left, 28¾ inches; from great trochanter to outer malleolus, right, 27⅝ inches; from great trochanter to outer malleolus, left, 27⅝ inches. The right great trochanter is 2½ inches above Nélaton's line. The head of the femur cannot be made out. All movements at the joint are normal, except extension and outward rotation. I suggested an attempt to increase the length of the limb by prolonged traction in bed, with the hope of eventually reducing the dislocation. Some months later the family came into town for this purpose, and the photographs, from which Figs. 1, 2, and 3 are taken, were made by Dr. Ogden C. Ludlow, on February 24, 1888. Two days later, on February 26, 1888, the old pattern of the Taylor extension hip-splint was applied and the leg elevated on an inclined plane. From this on for one year the child

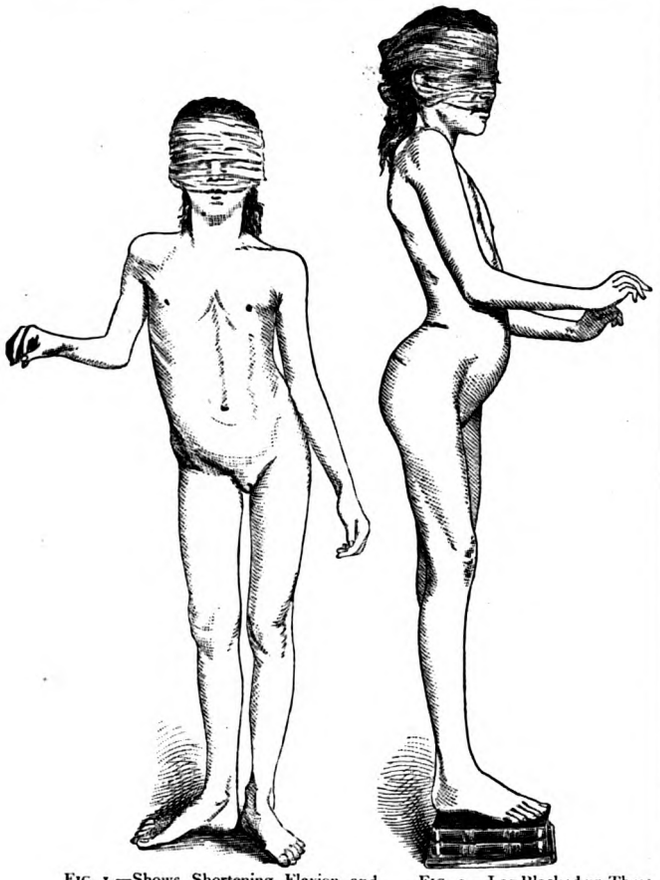

FIG. 1.—Shows Shortening, Flexion, and Outward Rotation.

FIG. 2.—Leg Blocked up Three Inches. Shows flexion of thigh, and lordosis of lumbar spine.

did not leave her bed, and no relaxation of the traction was once permitted. The inclined plane was lowered from time to time, and removed altogether after about six weeks. During the first two months the elongation of the limb was rapid, an inch in length being gained in that time; afterward it was slow. After eight months the tissues about the joint were thinned down sufficiently to make it possible to locate the head of the femur, which was found displaced upward and forward, lying almost directly below the anterior iliac spine. This position was confirmed by Dr. Frank Hartley and Dr. L. W. Hotchkiss, who saw her with me in January of the present year (1889). The head of the femur could then be brought around directly over the acetabulum. To do this, however, it was necessary to rotate the limb inward a quarter of a circle. It seemed as if, in the process of growth with the femoral head in the abnormal position, the neck had been twisted around to the front. As the parents would not consent to an operation to correct this twist, it was thought wiser to be satisfied with the increased length of the limb without a reduction of the dislocation, than to further attempt to replace the head, and thereby cause the foot to be rotated inward to a right angle with the other foot. To this end, then, a jointed splint was applied February 1, 1889, and the patient was allowed up. At that time the difference in the length of the limbs, as measured from the anterior superior iliac spine to the inner malleolus, was an inch; at the present time this has been reduced to one-half inch. (See Figs. 4 and 5, from photographs by Dr. Ogden C. Ludlow, on September 2, 1889.)

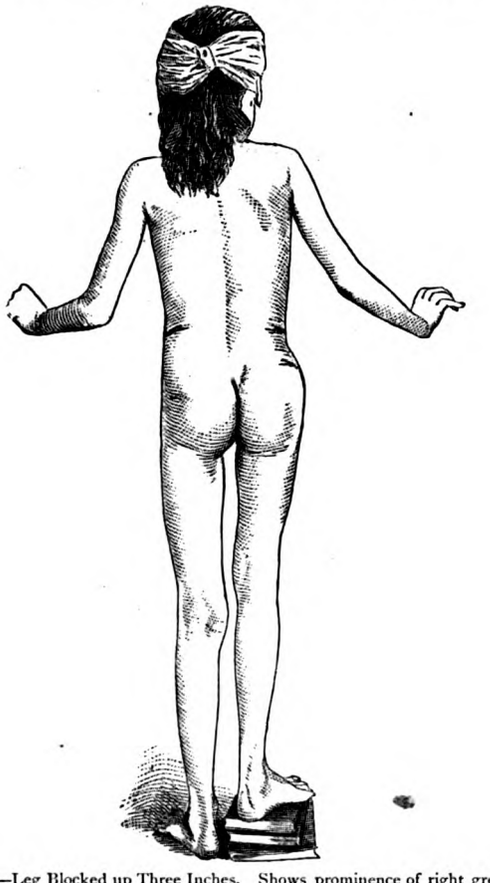

FIG. 3.—Leg Blocked up Three Inches. Shows prominence of right great trochanter. The upper lines are at the iliac crests, the lower ones at the great trochanters, showing the upward displacement.

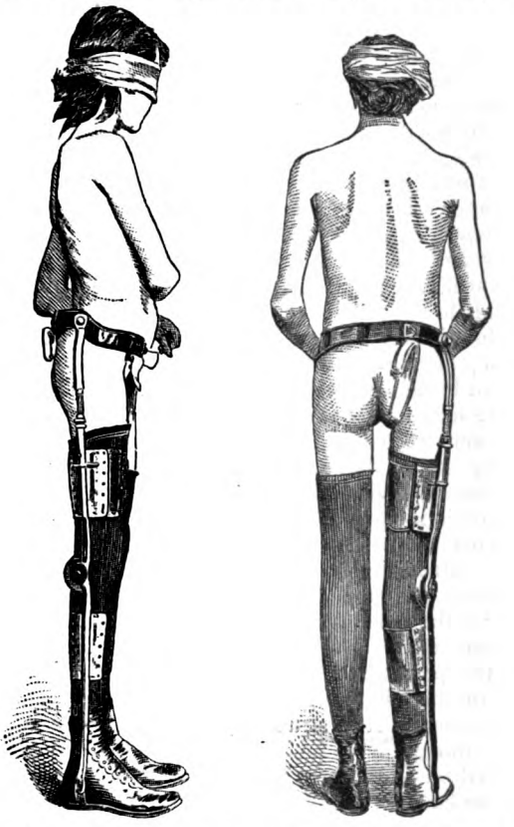

FIG. 4.—Same Position as Fig. 2, with the Jointed Splint Applied, but without Blocking Under the Foot. Shows reduction of lordosis and elongation of leg.

FIG. 5.—Same Position as Fig. 3, without the Blocking Under the Foot. Shows elongation of the leg and the reduction of the deformity.

This case is interesting on account of the direction of the dislocation (I have not been able to find another such case recorded) and because so much improvement resulted from the prolonged traction. I was disappointed, however, in not getting such a result as that reported by Dr. Buckminster Drown, in his case reported in 1885.

---

PULMONARY PHTHISIS IN SOUTHERN RUSSIA.—According to some statistics collected by Dr. Glavatski, the number of deaths from phthisis in Tiflis is about three hundred and sixty per annum, or nearly fourteen per cent. of the deaths from all causes.

## TUBAL PREGNANCY TREATED BY FARADIC CURRENT.[1]

By HENRY F. WALKER, M.D.,

NEW YORK

Mrs. S—— had been for some time a patient. She was twenty-three years of age, small, but of full figure, and had, when nineteen, borne one child. Her labor had been at that time a tedious one, finally an instrumental one, and convalescence had been tardy, though she regarded her final recovery as complete.

When her boy was three years old she became a patient of mine, and, as she and her husband greatly desired increase of family, I made an examination to ascertain, if possible, the reason of the acquired sterility.

A vaginal examination showed that there had been, at some time, plastic effusion about the uterus. That organ was slightly retroverted, and somewhat adherent by its posterior surface, so that it could not be replaced without some hazard. There was also a slight cervical laceration.

The existence of these pointed out the probable cause both of her slow convalescence after confinement and the subsequent sterility.

The examination was made not long before the beginning of the summer hegira, and treatment was suspended till her return in the autumn.

For the illness to be detailed I was first called to see Mrs. S—— September 24, 1888.

She had complained since August 12th. Menstruation should have occurred on the 12th, but was deferred till the 14th, when there was a slight show, which ceased after two days, to reappear, but only as a stain, through the remaining days of August and up to September 19th. She had just previous to this last date made the journey to town, about twenty miles. The flow stopped two days, and again began.

Besides the protracted, inconsiderable flow, the patient suffered from constant heavy pain and tenderness in the lower part of the abdomen, chiefly in the left inguinal region.

My partner, Dr. Swift, saw Mrs. S—— at her country home, August 27th, but she declined to have an examination.

September 8th, the date of menstrual epoch, she had, as she described it, a dreadful attack of pain accompanied and followed by abdominal soreness, but no increase of flow.

September 11th she had another very violent and persistent attack of pain. To her friends she seemed almost in collapse. "She looked like a dead person, deep circles under her eyes, and her face drawn and pinched, with cold forehead, nose, and chin."

September 14th, she was removed to town, and was seemingly somewhat improved.

September 24th, late in the evening, I was called to see Mrs. S——, and found her in pain, which, to my judgment, was very intense, though said to be less severe than some previous ones. It was relieved by the hypodermic needle with morphia; and I made a vaginal examination.

This showed the uterus to be in right retro-latero version, moderately fixed, and slightly enlarged. Save the slight enlargement, the condition of the uterus was the same as at the previous examination.

On the left side, lying low down, but easily separable from the body of the uterus, I could, by the bimanual method, readily define a semi-fluctuating tumor, in size and shape like the bulb of a Davidson's syringe, perfectly movable, but exquisitely tender.

This was described as the site of all previous pain and soreness.

I recognized it as a probable, extra-uterine tubal pregnancy. This, I must confess, had not, until examination, occurred to me as the condition likely to be found.

Inquiries made after this vaginal examination, brought out the facts of quite constant nausea during the month of August. The breast signs were also those of pregnancy.

I much desired a consultation with some of the ovariotomists, but I was afraid to have it. The consensus is so far in favor of an immediate laparotomy that I feared I might risk my patient's life were this treatment adopted. I determined to delay at least a day or two, treating the patient, and holding the surgical procedure in reserve. The sac, though very tender to touch, did not seem so tense as to excite alarm that it would burst at once. I waited for Dr. Thomas, who was still out of town, thinking he would agree with me in methods to be used.

September 25th.—With the patient on the back, brought to the edge of the bed in the French obstetric position, I introduced a metal ball electrode into the rectum, just beneath the tumor, and passed a current the full strength of a freshly-fitted Kidder's faradic one-cell battery through the tumor. The positive electrode was a broad sponge placed on the abdomen just over the tumor. The current was used for fifteen minutes, and was well borne by the patient.

Electricity was exhibited in this manner each day for five days.

September 26th, the day after the first application, the patient had no recurrence of severe pain, and felt relief from the general abdominal pain.

September 28th.—She had a very little pain, "but of a different character."

September 29th.—The facial expression has markedly changed, the anxious look has gone.

October 2d.—Dr. Thomas saw Mrs. S—— with me, and said the diagnosis was undoubtedly correct.

I used electricity October 1st, 4th, 9th, and 13th.

After the first application of electricity there was no increase of size of the tumor, but I could not appreciate its decrease until October 20th, when it was markedly smaller.

There was uterine discharge till October 20th. This was shreddy. It was not further examined.

This case adds one illustration to the established fact that in extra-uterine fœtations there is usually some uterine misplacement.

The position in which the enlarged tube was felt was due doubtless to the special displacement and adhesions. Otherwise the tube would have sunk into Douglas' cul-de-sac.

I report it, however, because it shows the efficiency of the faradic current in destroying the misplaced fœtus, and arresting sac-growth. Many a physician has a battery, and skill in its use, who has not the ability to do a successful laparotomy.

If the electrical current is effectual, it is without hazard to the mother, and in trying to do good it is most desirable not to do harm.

The only possible objection is delay; but if used before the sac is so tense that stimulated muscular action in the tube endanger rupture, it is safe.

At a later stage than my own case I should advocate its use, and if growth were arrested should postpone laparotomy till some threat of poisoning should come from the retained fœtus.

In early cases absorption is likely to be complete without septic change. In the case narrated, at last examination no trace of the tumor could be detected.

---

Late Pregnancies.—Dr. A. E. Mossman, of Westminster, Mass., writes: "As I notice continued reports of late pregnancies, I will contribute one. Mrs. C——, of Westminster, Mass., married late in life, at the age of forty-seven, and became pregnant and was delivered, at the age of forty-nine years and ten months, by forceps, of a male child weighing eleven and one-half pounds, in April, 1886."

# SURGICAL OPERATIONS FOR THE REPAIR OF RUPTURED PERINÆUMS.

By A. B. CARPENTER, M.D.,

CLEVELAND, O.

The great number of articles that have, from time to time, appeared in the medical press, taken together with the very exhaustive descriptions in the text-books on this subject, would seem to have covered the ground so completely as to scarcely warrant anything more in this direction; yet, there having appeared recently an article on this subject in a prominent English journal, the views of which, I believe, differ so widely from those of the American gynecologists, that I have ventured to defend some points that the author of the paper had taken the pains to so strongly condemn. Also to mention briefly some practical points that have come under my observation regarding the operation, as well as the after-treatment of the case.

Dr. Fancourt Barnes published a very brief article, together with a report of a number of cases, in the August number of the *British Gynæcological Journal*, wherein he described the repair of these injuries by the flap-splitting method as devised by Mr. Lawson Tait; and in order that I may do him no injustice, I will take the liberty of quoting him. He says:

"It is now four years since I first resorted to Mr. Lawson Tait's method of restoring ruptured perinæums by flap-splitting. From the first, the operation gave such satisfactory results, that I have treated every case which has come under my care by this method. . . . The old plan of paring away the mucous membrane of the vagina is most unscientific, as each time the operation fails the patient loses some vaginal tissue, until in some cases I have seen most of the posterior vaginal wall has disappeared. . . .

"I feel sure that medical men, who have only seen the results of the old operation, naturally hesitate to advise perinæorhaphy in cases of lacerated perinæums, because they know that it is always possible that the patient may be in a worse condition after the operation than before. . . . In cases where the rupture is incomplete, the operation is indicated to prevent the occurrence of cystocele, rectocele, or prolapsus."

Before going on to a consideration of the statements made by Dr. Barnes, I wish to say that I am an advocate of the denudation method for the repair of lacerations of the perinæum, and I know of no operation that gives greater relief, especially where the patient has suffered entire loss of the pelvic floor. That Dr. Barnes has secured good results by the flap-splitting plan, I would not for a moment pretend to question; yet when he asserts that "the old plan of paring away the mucous membrane of the vagina is most unscientific," a protest would seem not entirely out of order.

That Dr. Barnes found it advisable to adopt some method other than the "paring" one, is not at all strange, for he says he "feels sure that medical men naturally hesitate to advise the operation, because they know that it is always possible that the patient may be in a worse condition after the operation than before."

If his results were so unfavorable as one is led to infer from the foregoing quotation, it is not at all strange that he was inclined to abandon the "paring" and adopt the flap-splitting method. The failure of the former plan in his hands, I will venture to suggest, may not have been so much in the plan as in the operator, and that a careful observation of the general detail of the work would possibly have prevented the medical men from hesitating to advise, etc.

Be that as it may, I will try to place before the reader a few points to substantiate the position I have taken, viz., that for a majority of cases there is no method that will give the results that can be obtained from the denudation plan. But to obtain these results a scrupulous observance of a few points is imperative. What are the points? *a*. Antiseptic precautions. *b*. A smooth, even denudation. *c*. Continuous irrigation during the paring. *d*. Retaining the fingers in the rectum until the sutures are all in place and ready to be tied. *e*. The control of the bleeding from the denuded surface before the sutures are tied. *f*. The number of days the sutures are to remain before removal. *g*. The method of removing them. *h*. Attention to the bowels.

Fig. 1.—Dr. Howard Kelley's Rubber Cushion.

*Antiseptics.*—The patient should be placed in a lithotomy position, with the hips well forward to the edge of the table, and a rubber cloth, or, what is much better, a rubber cushion, as devised by Dr. Howard Kelley (see Fig. 1), placed beneath the hips to conduct the water into the jar beneath. By the use of such a contrivance any amount of water can be used, and at the close of the operation everything remains neat and tidy. The vagina should be first thoroughly cleansed by a hot solution of bichloride 1 to 3,000. This cannot be done with too much care. The index and the second fingers of the left hand are then introduced into the rectum, and the posterior vaginal wall is again cleansed. Two lateral retractors are then introduced into the vagina and held in place by assistants, and with the two fingers of the left hand still in the rectum, with a sharp pair of curved scissors in the right, the work of denuding is ready to be begun.

I usually make the denudation something after the plan of Simon (see Fig. 2). I have adopted this method

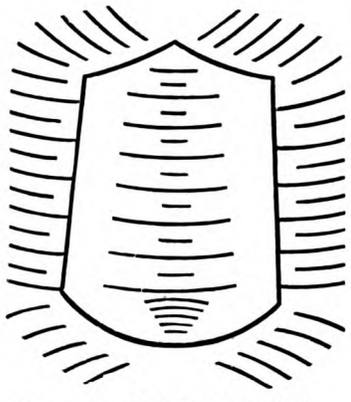

Fig. 2.—Simon's Method of Denudation.

for the reason that in my hands it has given me better satisfaction than any other I have tried. By this plan the vagina is narrowed to a greater degree, the uterus has a much better support, and rectocele and cystocele are less apt to follow than by any method with which I have had experience.

During the process of denudation, the bichloride is allowed to run continuously, and no sponge or other absorbing medium is made use of. Should the field become obstructed by a clot, the thumb of the left hand can easily brush it away. I carry the denudation up as high as I conveniently can, but always beyond the crest of the rectocele, and the entire field, as exposed by the retractors posteriorly, is made fresh. Great pains is taken that no uneven places be left, or, what is still more important, no undenuded points remain. As soon as the bleeding has been stopped the sutures are ready to be put in. With the two fingers still in the rectum, an assistant arms a needle of proper curve and length with a braided silk suture, and placing the needle in the holder, hands the same to the operator, who inserts it into the highest part of the denuded surface, taking pains to include only a small portion of the mucous membrane at point of entrance and exit of the needle; the remaining sutures are

then placed in position, the two fingers in the rectum acting as a guide for the needle (Fig. 3). When the sutures are in place and ready to be tied, the fingers should be withdrawn from the rectum and thoroughly disinfected. Attention is now given to the denuded surface, and if there is bleeding it must be arrested; much depends upon this point. Union by first intention is delayed when there is blood left and included in the closing of the wound.

Pressure for a short time with a piece of damp absorbent cotton or sublimate gauze, will usually leave the parts in perfect condition for closing. The cotton or gauze should be damp lest dry particles be left, thus proving irritating, and delaying union. When the sutures are all tied and the ends cut, a row of knotted sutures will be found to extend downward and backward to a point a little way in front of the cervix, and directly in the median line of the new pelvic floor. It is my custom to put in two sutures through the integument and new perineal body for the purpose of supporting the parts, and thus take the strain off the inner stitches. The work completed, the rectum is stretched, as the patient suffers less pain when this is done. The patient is put to bed and the water drawn with a catheter. A gentle douche of tepid water once a day, and a light diet, is about all that is required. I seldom fasten the legs together, and aside from the patient being instructed to be careful in all her movements, little restriction is placed upon her.

*Removal of Sutures.*—I consider the removal of sutures to be one of the most important points in the entire management of the case. When to remove and when *not* to remove, is a nice point. I believe many cases have proven

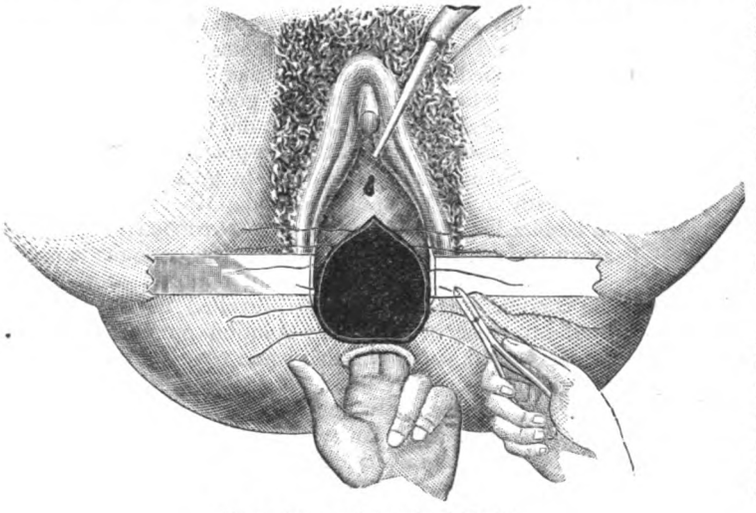

FIG. 3.—Manner of Suturing the Rectum.

failures that would otherwise have been perfectly successful, but for the fact that the sutures were removed too soon. There can be no fixed time or number of days given for the removal. Where union takes place with little or no pain, or where there is little or no inflammatory action, removal can take place several days earlier than when the opposite condition of affairs exists. I leave in my sutures from twelve to eighteen days, according to circumstances; preferring that considerable ulceration and cutting take place around the sutures than that they be taken out before strong adhesions have been formed. They can be left in four days too long much safer than taken out one day too soon.

*Method of Removal of Sutures.*—As will readily be seen, a row of sutures extend downward and backward in the vagina, and in some cases it is difficult to remove them without injury to the new perinæum. My method is as follows:

The patient is placed in the lithotomy position and an Allingham rectal speculum (see Fig 4) is introduced into the vagina with the fenestrated part directly over the row of sutures. The plug is withdrawn, when the sutures will readily be seen, and with a pair of locked handle dressing forceps, the ends are one by one seized and cut; the speculum removed, the perinæum not having been injured at all and the patient suffering no discomfort whatever.

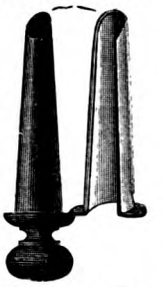

FIG. 4. — Allingham Rectal Speculum.

This method for the removal of sutures is, so far as I am aware, original with myself, and is in my opinion worthy of trial at the hands of men doing this work.

*Care of the Bowels.*—It is my custom to keep the bowels moving. I do this by means of a glycerine enema or suppository, and I find the patient suffers much less by having the bowels move on the second day after the operation, by the method herein described.

The results of my operations have been satisfactory, and I have seen my patients restored to health; and in closing will say, I do not think that I shall change to the flap-splitting method, neither do I consider the plan of "paring" as "most unscientific."

## SACCHARIN AS A MEANS OF ACIDIFYING THE URINE.[1]

BY ANDREW H. SMITH, M.D.,

NEW YORK.

WHILE it is usually not difficult to render an acid urine alkaline, our means for rendering an alkaline urine acid have heretofore been meagre and unsatisfactory. The mineral acids when taken into the stomach are chiefly eliminated by the intestinal mucous membrane, and the only way in which they affect the reaction of the urine is by liberating from their bases the organic acids which in the form of salts they may chance to meet in their passage through the system. The organic acids thus liberated may or may not find their way through the kidneys. As a matter of fact, they generally do not succeed in running the gauntlet. Indeed, so slight is their chance of doing so that in practice, in prescribing a salt of an organic acid, we leave the acid entirely out of consideration.

The only acid heretofore employed with any degree of confidence that it would get beyond the kidneys was benzoic acid. Even this does not reach the urine in its original form, but is converted into hippuric acid by the way. Nevertheless, it is in some degree useful in rendering the urine acid, but its action is not as certain nor as constant as might be desired.

When saccharin was first announced, it was mentioned among its properties that it was unaffected by the digestive fluids, and was eliminated unchanged in the urine. Some time later, having had occasion to manipulate somewhat with this substance, I was struck with its strongly acid property, and it occurred to me that so decided an acid, of such a stable composition as to resist decomposition in the system and electing the kidneys as its way of exit from the body, would supply exactly the agent required for acidifying the urine.

An opportunity to put this idea to the test was afforded by a patient in my wards at the Presbyterian Hospital. This was a boy suffering with transverse myelitis, whose urine, which required to be drawn with the catheter, was ammoniacal and very offensive. A few grains of saccharin administered three times a day promptly changed the reaction of the urine to acid, and did away completely with the offensive odor. Not only so, but the irritation of the bladder became less and the formation of pus was diminished.

Shortly after this I was in attendance upon a case of subacute meningitis in a child twenty months old. The

[1] Read before the Practitioners' Society of New York, November 1, 1889.

urine, which dribbled constantly into the diaper, was alkaline, and its odor, though not ammoniacal, was peculiarly sickening. Every effort was made in the way of cleanliness, but the atmosphere about the bed was extremely disagreeable. Small doses of saccharin were prescribed, and immediately removed the fetor, to the great relief of the parents and attendants.

On beginning my service at the hospital, on October 4th of this year, I found a young woman, aged eighteen, in the ward who was suffering from acute cystitis, apparently induced by suppression of the catamenia and the absence of an evacuation of the bowels for seven days.

She had then been ten days in hospital. On admission, three weeks after the onset of her illness, the urine was alkaline and contained a large amount of ropy mucus and pus. An attempt to wash out the bladder was abandoned, on account of the severe tenesmus excited. The contact of the catheter with the wall of the bladder caused hemorrhage.

Citrate of potassa was ordered, but gave no relief. When I came on duty I found the patient in so much distress that I suspected she had introduced some foreign body into the bladder. October 13th, finding the urine very alkaline, I directed the administration of five grains of saccharin three times a day. The following day the urine was neutral, and in four days more it was acid, and contained no mucus and but very little pus. October 23d, the urine was entirely normal, the symptoms had disappeared completely, and the patient was discharged cured.

It is probable that a part of the efficacy of saccharin in these cases is due to its being a powerful antiseptic in addition to its acid property.

### AN EASY METHOD FOR THE REMOVAL OF PLASTER-OF-PARIS APPARATUS.

By CHARLES H. RICHARDSON, M.D.,

NEW YORK.

I HAVE used of late a plan in the removal of plaster and starch bandages which seems to do away with the annoyance to the surgeon, and the discomfort, not to say distress, to the patient, attending removal by the shears.

It consists simply in the application of a piece of wire under the bandage, which is made to out its way out when removal of the apparatus is desired.

The limb is prepared for the bandage in the usual manner, either by the application of a flannel roller or by being well anointed with vaseline. A fine steel wire is then laid the length of the limb, in the situation that it is desired subsequently to cut, and firmly held in that position by an assistant. This is secured by a few turns of the plaster bandage, and the apparatus finished in the ordinary way.

The wire should project four or five inches at each end of the bandage, so as to afford sufficient for a firm hold when the time comes for removal. These free ends of wire may be bent down after the casing is completed, to prevent the annoyance to the patient which the sharp ends might otherwise produce.

When the removal of the appliance is desired it is necessary to have the patient rest his limb on a table in order that it may be perfectly steady, and while the lower projecting end of wire is held firmly in place, to prevent its slipping underneath the bandage, the upper end is seized by a pair of pincers and by firm traction made to cut its way through the whole length of the casing. The apparatus may now be bent back and removed, the operation having caused no discomfort, which can hardly be said of the combined prying and cutting with a pair of plaster shears.

To two points would I like to call attention before I close. The first is that no attempt should be made to remove the casing until it is completely and entirely dry. The wire will not cut through wet bandage.

The second is, that while one wire will cut through the ordinary light dressing, such as is used on the arm, yet when an extra thickness is given to the apparatus, as in a plaster jacket or in an appliance to the lower limbs, I would recommend that two or even three wires be used, to make the cutting easier and more sure.

If more than one wire be used, the second is laid as nearly over the first as possible, after a few layers of bandage have been applied, and a third over this if it be deemed necessary. Thus a layer of plaster and bandage will intervene between each of the two or three wires.

The method of cutting is evident. It is done in sections, by pulling the wires in inverse order to that in which they were laid.

427 LEXINGTON AVENUE.

### LIGATION OF THE ANTERIOR TIBIAL ARTERY FOR TRAUMATIC ANEURISM.

By J. R. WILKINSON, M.D.,

GREENVILLE, S. C.

MR. P. M. B. D——, aged thirty-eight, a shoemaker; has been strong and healthy all his life, but has been drunk, with but few intervals, for the last twelve years. About October 1, 1887, while drunk, he picked up a scythe-blade, and accidentally thrust the point into his left leg, at about the juncture of the upper and middle third of the tibia, about an inch to the outer side of the spine. This was followed by considerable bleeding.

He stopped me on the street the following day for advice, upon which I told him to go home and lie down, keeping his leg elevated. But he did not do so, and I declined to assume any further responsibility in the case. On November 6th I was sent for in great haste, just as I was ready to go to Sunday-school. Mr. D—— was said to be bleeding to death, and when I reached him he was about to faint from loss of blood. I at once made pressure on the femoral artery, but not realizing at the time the conditions that existed, I controlled the hemorrhage by the free use of Moonsil's solution on cotton to the gaping wound, supposing that some vessel of medium size had sloughed. One week later the third hemorrhage came on, and was controlled as before. He lost not more than half the usual quantity of blood.

I then saw him every day, when on the 22d the fourth hemorrhage came on, and was controlled as previously. At this time a pulsating tumor of considerable size had developed, and there was a well-marked bruit.

After careful examination I decided that an operation was necessary, and on November 23d invited Drs. Wallace and Bailey to assist me. Against the opinion of these gentlemen, I decided to make an effort to save the leg. I made a long incision, about five inches in length, directly over the tumor, through integument and superficial fascia, which opened into a mass of coagulated blood and pus.

Many of the muscles of the calf were dissected apart, this same mass being packed in between them, requiring much time for its removal. A quart would, I think, be a low estimate of the amount of this material. The tumor, upon examination, proved to be an aneurism of the anterior tibial artery, about two and a half inches long, with a diameter of about one inch. (I say *about*, because my office-boy threw it out of the basin before I had made actual measurement.)

I removed the tumor after ligating the anterior tibial artery, about one inch above and below it, with carbolized catgut. The wound was thoroughly cleansed with hot carbolized water, dusted with iodoform, and wrapped in a thick cotton dressing.

November 24th.—Patient did well, except that there

was some suppuration, until November 28th, on which day a secondary hemorrhage occurred.

When I reached the patient he was almost exhausted, and seemed on the verge of going off in a swoon from loss of blood. Hemorrhage was controlled as on previous occasions until I could get a bandage and compress and assistants, which took some time, as it was late on Sunday afternoon.

The patient being anæsthetized, the whole wound was laid open and cleansed with carbolized water (1–40), after which it was thoroughly sponged out with spirits of turpentine. The artery was found to have sloughed at point ligatured.

Believing that my mistake lay in the fact that I had ligated the vessel in an open suppurating wound, I cut down on it through fresh tissue about one inch from where it emerges from the interosseous space, placed a silk ligature around it, and sponged out the freshly made wound with spirits of turpentine, with which I had previously washed my hands. I then brought the parts together and held them by deep silver sutures.

The patient now did well until December 31st, when it was found that a large pocket had formed in the calf of the leg where the muscles had been dissected up prior to the first operation.

I made an incision four inches in length, opening up the pocket, which proved very effectual in reducing local irritation, also general œdema of the whole leg and foot.

January 13, 1889. I put the patient on chloride of gold and sodium, gr. $\frac{1}{15}$, t.i.d., hoping by its effect to destroy the desire for whiskey.

February 9th.—Walked out on street to-day. Leg and foot still somewhat œdematous. Collateral circulation going on well and gradually improving.

September 26th.—At this time the patient is still following his trade. Has good use of the whole leg. Collateral circulation is well established, and he has no trouble whatever. I advised him to wear constantly a leathern fender as a protection to his shin, telling him that any scratch would be hard to heal. He did not, however, believe me until I had to keep him in bed for a week or two on account of a slight bruise which made an ugly ulcer.

The points in the case which I would call special attention to are:

1. The external coats of the anterior tibial must have been incised at the time of injury, leaving the inner ones intact.

2. The several hemorrhages and infiltration of surrounding tissues to such an extent *after* dilatation of the walls of the vessel.

3. The mistake made in ligating an important vessel in an open suppurating wound.

4. The use of spirits of turpentine as a styptic and disinfectant.

5. Thorough irrigation in such cases twice daily with hot carbolized water.

## A LOST DRAINAGE-TUBE.

Dr. DeWitt Hitchcock, of Long Island City, writes: "Since it is by recording the unfortunate errors in the treatment of cases that we are cautioned and put on our guard in the management of future similar ones, I relate the history of a very interesting case which occurred in my practice recently. On December 15, 1877, Edward Fay, aged six years, Long Island City, was seized with pleuro-pneumonia. The family physician was summoned, but the disease was severe in its attack, and, in spite of good care and treatment, left the little patient with empyema.

"On February 19, 1888, I was called in consultation, and for the purpose of aspirating if I concurred in diagnosis. I found the patient anæmic, elevated temperature, rapid pulse and respiration, profuse perspiration, together with all the physical signs of empyema. I aspirated and drew off thirty-two ounces of purulent matter, and recommended free incision. I left the case in charge of the family's physicians, and a few days later they made a free opening into the pleural cavity, through the left seventh intercostal space, posteriorly, and introduced an ordinary No. 12 rubber catheter for drainage-tube. On the afternoon of the same day the wound was dressed by the attending physician, and the mother, as well as the physician, noticed that the catheter seemed a little shorter than when introduced, but they thought that probably if any was gone it had been burned with the oakum dressing. Drainage was kept up about three weeks, when the tube was left out and the wound closed up. But the patient's condition grew rapidly worse; about eighteen days later they opened the cavity in the same place, and a profuse discharge of pus followed. At this time, fearful that a small piece of the catheter was lost in the pleural cavity, search was made, but availed nothing. Drainage was kept up until the following November, when it was discontinued and the wound again allowed to heal. On Christmas-day following (December 25, 1888) it opened of its own accord and discharged freely. A drainage-tube was again inserted, and continued up to October 8, 1889, when he was brought to my office and examined by Dr. G. B. Strong and myself. The little fellow was very distrustful, and had lost all confidence in physicians and the 'healing art,' so much so that we could only get the history as related above, and note his general condition. He was in very delicate health; emaciated; poor appetite; weak, rapid pulse; slightly elevated temperature; night-sweats; more or less swelling of the feet (but no albuminuria), and a troublesome cough. We concluded that there either was necrosis of the rib, or else some part of the old tube remained to keep up irritation and the continual discharge. We recommended an operation as soon as his health could be a little improved, and after a course of tonic treatment we operated October 19, 1889. The patient was etherized, and an incision made to examine the rib. Finding no sign of dead bone, the incision was enlarged into the pleural cavity sufficient to admit the index finger, and thorough exploration made. After searching in every direction, and passing the finger to the extreme lower part of the pleural cavity, we thought we could detect a foreign substance, and with the dressing-forceps, but not without considerable force to loosen it from its partial impaction, we removed five and three-eighths inches of the lower end of the catheter introduced March 19, 1887, for the purpose of drainage. The wound was dressed with antiseptic precautions, and at the present writing he is improving rapidly, with good prospects of a speedy and permanent recovery."

## CEPHALIC VERSION EIGHTEEN HOURS AFTER RUPTURE OF THE MEMBRANES.

Dr. W. Clayton Dukes, of Memphis, Tenn., reports the following case: "When the patient was seen for the first time it was about sixteen hours after the membranes had ruptured. Upon examination I found an entire prolapse of the left arm, the shoulder was firmly engaged between the pelvic bones, the head was forced backward over the left scapula, the face looking to the right and approximating a line drawn horizontally across the pelvis. Violent contractions, tonic in character, were present from the administration of a dose or two of ergot given by a woman in attendance. The uterus was firmly retracted upon the child, and the pains were frequent and expulsive. The patient was thoroughly anæsthetized, and the child's forearm was flexed upon the arm, which was used as a fulcrum and pressed backward and upward as gently as possible until it was returned into the vagina, when it was rotated and passed gently backward underneath the child and to its normal position at the side. After this three

fingers of the right hand were placed above the head of the child and pressed gently downward, the thumb resting upon the left shoulder and pressing backward. The head was gently rotated and brought into the position of a normal labor, and the child was born on the following morning, about three o'clock, after one or two expulsive pains. The tonic contraction of the uterus made this an extremely difficult manipulation, but as the feet could not be reached there was nothing else to do. In this case I received most invaluable assistance from my friend, Dr. W. B. Winkler, and take this occasion to express my grateful thanks."

## Progress of Medical Science.

AUTO-INFECTION IN PUERPERAL CASES.—At the last meeting of the German Society for Gynecology, Kaltenbach expressed his belief that while in the great majority of cases infection comes from without, yet the innocuous bacteria found in the vagina may invade the uterus and become pathogenic, especially if the tissues be mechanically injured or destroyed during labor, and absorption of the products of retrograde metamorphosis follows (*The American Journal of the Medical Sciences*, October, 1889). The attempt to sterilize the genital tract is unnecessary and meddlesome, but a vaginal douche of bichloride of mercury, 1 to 3,000, had done him good service, and is used to advantage in protracted cases. The necessity for intra-uterine douches becomes very infrequent when prophylactic douches are given. Fehling considered many cases of fever in puerperal patients, examples of the absorption fever common in surgical patients, in whom absorption of disintegrating albuminoids, with or without germs, was not rare. In the presence of an abundance of such matter, harmless germs often become virulent. He lays most stress on disinfecting the external parts; the vagina is irrigated only when foul lochia are present. Should the placenta or chorion be retained, interference is demanded. In all labors care is taken that the membranes do not rupture too soon; that perineal tears are avoided by episiotomy; and that the forceps is used before the tissues have been injured by pressure.

IMMUNITY AND IMMUNIZATION.—Dr. H. Buchner has recently published a new study of this subject, and *The Sanitarian* gives the following *résumé* of it: Immunity in its full meaning signifies a condition of the body which permanently opposes the development of infectious processes. But there are conditions which act transiently in the same way against the danger of infection already existing. Buchner exemplifies this by a person attacked with typhus. In this case the disease, the continuous multiplication of bacilli, is not terminated before all tissues acquire transient immunity against the fungi. But what are the means by which the organism acquires immunity in a permanent or transitory way? To answer this question Buchner first refers to Pasteur's protective inoculation, the actual efficiency of which is generally admitted at the present time. Buchner calls it a great triumph that it should be possible to immunize a living organism in this way without hurting its tissues. Again, another means of immunization comes from France. Chamberland and Roux have injected intra-peritoneally the chemical substances of bacteria (ptomainia) in experiments on animals affected with malign œdema and with anthrax, without taking the bacteria themselves. The animals were actually rendered resistant to inoculation with living bacilli of the corresponding disease. This discovery is practically very important, inasmuch as the effects of chemical agents for the purpose of immunization are certainly more accurately measurable than those of living fungi. Theoretically, the discoverers neglected drawing the necessary consequences from their results, and this has been done by Buchner with zealous energy. He prefaces his developments with a discussion of the means by which transitory immunity may be obtained. It might be possible to neutralize specific ptomaïnes in the organism by means of certain substances, just as Behring succeeded in decomposing the ptomaïne of cholera-vibrios, cadaverne, by means of iodoform. Nature uses inflammation as an antidote against the invasion of fungi. Ten years ago Buchner pointed to this reaction of the organism by which it acquires transient immunity, but at the present day he disposes of proofs for his hypothesis. In a former paper, Buchner has described anthracic pneumonia produced by the inhalation of anthrax bacilli. Its symptoms are those of a sero-fibrinous hemorrhagic pneumonia. In the alveoli there is found an exudation abounding in cellules and an immense quantity of anthrax bacilli. On the other hand, the pulmonary capillaries and the larger vessels were absolutely devoid of bacilli, the spleen containing only a very few of them. For the purpose of investigating the modus by which the agents of infection are arrested in their further invasion, Buchner has lately instituted some experiments which led to the conclusion that "inflammatory reaction not only possesses the power of arresting the passage of bacteria through the pulmonary surface, but actually to cause degeneration of the infectious bacteria, and consequent destruction." We are not permitted here to give in detail the interesting experiments which Buchner, jointly with Dr. Schickhardt, has performed on animals infected with anthrax bacilli. The microscopical result confirmed Buchner's hypothesis that inflammation originates in consequence of the bacillus, but that conversely, once originated, it induces degeneration in the bacillus, and may doubtless cause its complete decay. The latter hypothesis is corroborated by the shapeless agglomerations of granules which are found, and which represent a transformation of the bacilli. In accordance with the fact of an antibacterial, immunizing action of inflammation, Ribbert and Lahr have ascertained, after injecting staphylococcus avoreus into the trachea, that the local inflammation prevents the bacteria from penetrating into the organism, and subsequently causes them to degenerate and to die. Emmerich, and similarly Paulowski, have tried already to utilize these experiences in a practical way, the former by his experiments with injection of erysipelas-cocci in animals affected with anthrax; the latter by establishing the fact that even simple saprophytic fungi have a restraining curative influence on simultaneous anthracic infection. It may be possible in some other way, as tried already by Landerer by means of Peruvian balsam, to create in the organism a condition of excitation which might be used as a means of immunization. Through what kind of chemical and microscopical conditions an inflammatory excitation, or immunity acquired by protective inoculation, may act deleteriously on the bearers of infection is explained on the results of Metschnikoff's well-known phagocytic theory. In Buchner's opinion this theory constitutes one of the greatest additions to our morphological and physiological science of infectious processes. Metschnikoff's doctrine, opposed from many sides, draws its principal importance from the fact of having demonstrated that viable, pathogenic bacteria may indeed be devoured by cellular elements. It explains how leucocystic and other cellular elements migrate into certain tissues in a condition of inflammatory excitation and exposed to infection, there display their phagocytic action. It is true, Buchner does not consider everything explained by this process alone. On the contrary, a certain chemical reaction and concentration of the different tissue-fluids seems to be necessary for the debilitation and destruction of the fungi. Buchner, on the ground of experiment, is inclined to suppose the existence of fluid substances which, formed by the febrile process, have an antibacterial action. This explanation being quite satisfactory for transient immunity, there are other processes to be considered in permanent immunity. Voit's experiments in Buchner's laboratory have recently furnished the proof that the organism possesses in the living blood-plasma chemical properties of

this kind, deleterious for bacteria. Living blood, generally, is an unfit alimentary substratum, but by a change of its quality it may become a proper medium, and in this case a morbid affection of the organism would take place; the period of incubation would then be the time in which the blood is still possessed of those properties which arrest the bacteria in their growth or, possibly, even destroy them. Immunity, then, would represent a permanent power of the organism to maintain the period of incubation. The question, in what way transition to actual morbidity is prevented, is answered by Buchner, availing himself of the experimental results obtained by Chamberland and Roux, by the suggestion that it is the adaptation of the organism to the specific virus which makes the latter gradually lose its pathogenic properties. This very supposition of adaptation underlies protective inoculation with attenuated specific fungi, as well as with dissolved specific products of decomposition.

Suppuration without Microbes.—In a paper read before the French Association for the Advancement of Sciences, M. Steinhaus, of Varsovia, combats the notion which has of late been gaining a strong hold of the professional mind, that without microbes there can be no suppuration. He cites the experiments of Straus, of Bary and Christmas (among others), as giving results entirely contradictory to the doctrine that suppuration is absolutely dependent on microbes. He has himself made two hundred and forty-five experiments on dogs, cats, guinea-pigs, and hares. As pyogenic agents, he has employed chloride of zinc, chloride of mercury, pure mercury, nitrate of silver, oil of turpentine, croton-oil, and culture broths, which had contained the staphylococcus pyogenes. All these substances were injected under the skin of animals, after having previously been sterilized in Koch's apparatus. The results were as follows: In the guinea-pigs and hares, only the chloride of mercury, mercury, and the sterilized broths produced suppuration, while in the cats and dogs, besides these substances, oil of turpentine, petroleum, and nitrate of silver produced it as well. These results compelled the conclusion that suppuration may be provoked by sterilized chemical bodies, and that it is possible without microbes.—*The Boston Medical and Surgical Journal.*

A New Turpentine Eruption.—Dr. Feiber, of Aix-la-Chapelle, furnishes a clinical example of the rare condition of an œdematous and papular erythema following the internal administration of a turpentine preparation. The patient was under treatment for subacute gonorrhœa, and was taking eight grains of the essence of turpentine twice daily. On the ninth day of the treatment, that is, after the use of about seventy grains of the turpentine preparation, the patient complained of severe pruritus. On the following day an erythema, consisting of small, acutely pointed papules of a bright red color, some of which were excoriated by scratching, was found to cover all the surface of the body excepting the head and face, being more pronounced on the lower than on the upper limbs, and specially intensified on the abdomen and buttocks. The pruritus and rash disappeared in three days on the cessation of the turpentine preparation. Being desirous of ascertaining if the turpentine would again produce the erythema, Dr. Feiber again prescribed it. On the fourth day violent itching returned, accompanied by an eruption of similar papules; but in addition to these there were noticed on the abdomen and buttocks small red, slightly raised spots, with patches about the size of a half-dollar of the same bright red color, both in their centres and in their peripheries. The urine was normal, and the patient felt well. Dr. Feiber remarks that, whereas the first eruption was exclusively a pure papular erythema—roseola—the second, on the contrary, was a mixed form of œdematous and papular erythema, an eruption described now, as far as he knows, for the first time as consequent on the administration of turpentine.—*The British Journal of Dermatology.*

Vertebral Pain: A New Form of Gastralgia.—Dr. Buch, of Finland, in a paper on this subject, states that he has recently discovered that, in the great majority of cases of so-called cardialgia or gastralgia, pain, similar to that of the attacks, can be elicited by pressure on the vertebral column, through the abdominal parietes, while abdominal pressure elsewhere is painless. The sensitiveness to pressure sometimes extends the whole length of the accessible portion of the vertebræ, in which case some portions are usually more tender than others, or it may be confined to certain spots, which are not always in the immediate neighborhood of the apparent seat of the pain. Thus he found that pain in the epigastrium and lower sternal region was most frequently produced by pressure about an inch below the umbilicus. It is often associated with dyspeptic symptoms, and sometimes with painful pulsation of the abdominal aorta. He considers the affection to be generally due to neurasthenia, sometimes to chlorosis and uterine inflammations. Anatomically, he believes the seat of the pain to be in the hypogastric and aortic plexuses of the sympathetic with their connecting branches. As a palliative for the attacks he has found most benefit from hypodermic administration of antipyrin. The cure, of course, must depend on treatment of the fundamental affection.—*American Journal of Insanity*, October, 1889.

The Physiological Resistance of the Peritoneum to Infection.—In the past year hardly a more interesting series of experiments has been made in the interest of surgical pathology than those of Rinne (*Archiv für klinische Chirurgie*). Practically and clinically it has been demonstrated that the peritoneal cavity under certain unknown circumstances has the power of taking care of a vast amount of filth. It remained for Rinne to harmonize observed clinical facts with *a priori* deductions. He found that large quantities of septic material and pure cultures of pyogenic bacteria were absorbed, although injected daily into the peritoneal cavity of animals, provided that the peritoneal surfaces were uninjured. The injections produced only mild symptoms in direct proportion to the quantity of septic material used, and in no case was there more than a moderate rise of temperature. The results were very different when there were coincident defects in the peritoneum, exposing the subperitoneal connective tissue to infection. Then there invariably appeared progressive suppurative peritonitis going out from the infected connective tissue, which usually terminated fatally. The practical import of these experiments can hardly be overestimated. They explain why the escape of pus into the peritoneal cavity from the rupture of a pyosalpinx is not necessarily fatal if the tube is promptly extirpated, and the wound and stump properly treated. They point out that the incision is the point of greatest danger in all abdominal operations, and they would indicate that too much care cannot be taken in coaptating the peritoneal edges of the wound. They explain why the removal of abdominal tumors is so much more dangerous after adhesions have taken place, because the resulting denuded places offer less resistance to the invasion of septic bacteria. They explain the success of those operators who disregard the dictations of scientific bacteriology, and also the recovery of patients after abdominal section by horned animals. They teach us to consider cautiously the evidence presented by the statistics of operators, and await the demonstration of more exact methods as to the import of their results. They warn us that clinical evidence is inadequate to overthrow the deductions of experimental physiology and pathology, and that our time is provided with methods of precision which are yet imperfectly improved. They beckon the ambitious into fields of activity and thought far less crowded, though more promising than the operating room and the dead-house. The resisting and absorptive power of the peritoneum is beyond that of any other serous cavity. This is as we should expect. The peritoneal surfaces are only a line

distant from the most filthy and prolific culture-medium about the body. It is connected with this seething and turbulent mass by the most active absorbent lymph-channels. Doubtless it is frequently invaded by septic bacteria from the intestinal contents. From these frequent invasions an immunity has been developed which has been perpetuated and transmitted by the working of the ordinarily recognized laws of evolution. Again, we are taught to consider the causes which determine the localization of infection as more important than the quantity and quality of infective material. Doubtless traumatism is one of the most important of these causes, but we must not forget that the depression of the general temperature of the body, the interference with nutrition, and general *malaise*, frequently observed after operations, are factors which may speak for the life or death of our patient. Not only should the abdominal section be made with the greatest attention to cleanliness, but the peritoneal edges must be accurately coaptated, the operation must be done with the greatest celerity and delicacy, and depressing influences of starvation, over-medication, and deprivations of every kind must be avoided if we would eliminate all those causes which determine the localization of that infection, which is still the greatest danger the operator has to meet.—*The Journal of the American Medical Association*, October 12, 1889.

The Symptomatic Indication and Therapy of Residual Urine.—According to Dr. Casper, under the term residual urine we understand that portion of the urine which, after urinating, remains behind in the bladder. The healthy man has no residual urine—that is to say, he empties his bladder at each act with the exception of a few drops. We possess in the residual urine a measure to indicate the functional condition of the bladder. The lack of functional capacity can be caused by a variety of circumstances—defect of innervation of the bladder, embarrassed or obstructed flow of urine. Furthermore, degenerative or functional change in the muscles of the bladder may cause a lessening of the contractility of the vesical detrusor (atony of the bladder). Persistent abnormal frequency of urination always leads to the presumption of residual urine being present. The quantity of urine voided shows only the power of secretion on the part of the kidneys and not the expulsive power of the bladder. Involuntary flow of urine almost always indicates an excessive collection of residual urine, a retention of urine, but not incontinence. It is doubtless true that in certain cases of chronic retention catheterization is absolutely to be warned against, but the author endeavors to free it from the suspicion of causing in many cases severe cystitis and even the death of the patient. The cystitis is caused in these cases by the introduction of infectious material, while the sudden death is due to the operation having been put off too long. The catheter should be thoroughly cleansed and disinfected and introduced with the utmost care. Soft instruments are preferred. For anointing the instrument, equal parts of lanolin and vaseline well rubbed up together are recommended.—*Med. chirurg. Rundschau*, August, 1889; *Journal of Cutaneous and Genito-Urinary Diseases*, October, 1889.

Abnormal or Contrary Effects of Antipyretics.—Professor Heuchen, of Upsala, has frequently observed in the academical hospital the so called contrary effects of antipyretics, mostly of chinolin, but also of antipyrin, antifebrin, and phenacetin (*The Lancet*). He believes the increase of temperature on administering these drugs to be due to a variety of causes. In some of his observations there might have been a spontaneous rise of temperature, while in others the symptom is explained as being due to an irritation communicated from certain parts of the body. Professor Heuchen mentions several cases in which the administration of chinolin resulted in vomiting or diarrhœa. In these, however, the doses had been large enough to be considered toxic. A similar explanation is suggested of a case mentioned by Laache, in which an extensive rash was produced, the temperature sank, and the patient became collapsed. A rash was observed by Heuchen only in cases in which chinolin had no abnormal action on the temperature. The best explanation of this singular occurrence is, however, probably to be found in the observation of Giegel of Wurzburg, who states that on administering antipyrin or antifebrin the temperature always first rises and then rapidly falls upon the appearance of diaphoresis. He thinks that in those cases in which the diaphoresis is slow in appearing the rise in temperature has probably also lasted longer, so that this contrary effect is due solely to the absence of diaphoresis.

A New Cardiac Remedy.—The alkaloid discovered in the common gorse, "whin," or furze, of Europe (*Ulex Europæa*), termed ulexine, is of a most powerful character. It appears to arrest all voluntary movements and reflexes by paralyzing the motor tract of the spinal cord and the trunks of the motor nerves. The heart-muscle is paralyzed, though preliminary thereto there is an increase of arterial pressure. Further, it possesses a diuretic action similar to that of caffeine, but more definitely marked.—*The Medical Age.*

Clinical Significance of Albuminuria.—In the course of an article on this question the *Lancet* says: "It seems to us that rather too much has been made of those cases of albuminuria appearing under forced and unnatural conditions in health. Extreme physical fatigue, intense mental excitement, and some other causes, have been shown to be capable of producing temporary albuminuria, and this fact has been much relied upon by those who advocate what may be regarded as the newer views upon the subject. It is doubtful, however, if we are justified in drawing any definite conclusions from symptoms appearing under conditions entirely without analogy to those usually prevailing. A person ascends an Alpine peak, and has an attack of hæmoptysis. This only proves, what no one ever doubted, that a sudden and extreme alteration in the conditions of blood-pressure may cause hemorrhage, but it helps us little, if at all, to determine when hæmoptysis occurring under normal conditions is due to organic disease, and when it is independent of such. A parallel reasoning may possibly apply to those cases of albuminuria occurring under peculiar and highly abnormal conditions. The fact is interesting and worthy of careful note, but we must be very chary of reasoning confidently from it. The abstruseness of the subject is shown by the fact that even the presence of casts, so long relied upon as absolutely diagnostic of organic disease, does not justify any final conclusion. Their presence is very noteworthy. If they are numerous and constant the probability of Bright's disease becomes almost a certainty. Their character is capable of affording important guidance. But the remarks already made upon albumin apply almost without alteration to casts—viz., that while their presence is highly significant, we must note that presence as only a most important element in our diagnosis, and not as conclusively determining the whole question. Cyclic albuminuria, or cases in which albumen appears in considerable quantities at intervals, the urine being free from it in the interim, has attracted much attention since it was first described by Dr. Pavy. It would appear, as might almost have been conjectured, that such cases are somewhat favorable relatively, and perhaps approach nearest to meriting the designation of "functional." This term reminds us how much this question has been one of nomenclature. Whether "physiological" albuminuria is a justifiable expression has been hotly debated, and it has been argued with much force that we might as well talk of physiological epistaxis or physiological hæmoptysis because bleeding from the throat and lungs may occur under abnormal conditions in health. The correctness of the analogy may be contested, but probably Dr. Gairdner is right in preferring the expression "functional" albuminuria. This, we presume, involves no hypothesis be-

yond the assumption that albuminuria occurs apart from discernible organic disease, and that this occurrence must be due to some aberration of function. These assumptions are hardly any longer contested. We may sum up the present state of medical opinion on this most difficult question by saying that the persistent presence of albumin in the urine is a most grave symptom, and in the great majority of cases is indicative of organic renal disease; that, nevertheless, this rule has some rare exceptions; that we are only very slowly seeing our way to the detection of these exceptions, but that we may best hope to avoid error by invariably taking a comprehensive view of each case, by allowing each symptom its due weight and avoiding the drawing of conclusions from one symptom only, by postponing any important decision until time may have helped to the clearing up of difficulties, and by deriving all the help we can from considerations of history and etiology.

Fatal Result of a Wasp-Sting.—A farm-laborer, aged twenty-eight, was stung on the right side of the neck by a wasp, on August 29th last. He took no notice of it; but the next day, late in the evening, both sides of his neck began to swell, and on Saturday, the 31st, things looked so serious that a physician was sent for. He found the neck, cheeks, lower jaw, and even the pectoral muscles attacked with acute cellulitis. Careful inquiry elicited the fact of the wasp-sting, and that when he received the lesion he had a boil under his left ear; also that, though a very healthy-looking and well-nourished man, he was sadly troubled with constipation, and a member of a family among whom boils and abscesses were very common—thus evidently showing a natural tendency to suppurative mischief. The treatment consisted of the use of antiseptics, both internally and externally, hot poultices, milk *ad libitum*, stimulants as far as could be tolerated, and plenty of fresh air; but, in spite of all, septicæmia, with violent rigors and delirium, supervened on the sixth day, and he died on the ninth day after the reception of the sting. No abscess formed, but the cervical tissues were very much indurated. August 29th was a very hot day, and, following as it did a period of rainy weather, the conditions were very favorable to the rapid decomposition of dead organic matter, whether animal or vegetable, and it is highly probable the wasp may have been feeding on some putrescent material previous to stinging the unfortunate man. As he had nothing whatever to do with the cattle, and as all the horses and cattle on the farm where he was employed are quite healthy, it is clear this was not a case of anthrax or malignant pustule, but death due to a wasp-sting received when the system was not healthy.—*British Medical Journal.*

French Views on the Electrical Treatment of Uterine Fibroids.—A long discussion has lately taken place at the Société de Chirurgie on the electrical treatment of uterine fibromata compared with the other methods (*The Boston Medical and Surgical Journal*, October 10, 1889). The debate was introduced by Dr. Lucas-Championnière, who read a note giving the results obtained by him, conjointly with Dr. Léon Danion, a well-known electrician in his service at the Hôpital Saint Louis. If there still remains a good deal to study on this subject; if there are other indications to be investigated; if it is true, in fine, that surgery can alone pretend to the radical cure of uterine fibromata—the conclusions of Dr. Lucas-Championnière are not the less very favorable to the treatment which he classes, without hesitation, in the first rank among the medical means employed in the treatment of this class of affections. This communication provoked a discussion in which several members of the society took part—among them may be named Drs. Bouilly, Schwartz, Kirmisson, Segond, Trélat, Le Dentu, Berger, and Tillaux, all well-known surgeons, who have supported, and some of them have even accentuated, the conclusions of Dr. Lucas-Championnière. Others, a few in number, with Drs. Terillon, Polaillon, and Terrier, expressed themselves as little or not at all favorable to this mode of intervention. That which gives a great value to the judgment of the principal members of the Société de Chirurgie is, that nearly all of them are distinguished laparotomists, and that the surgical successes of Dr. Lucas-Championnière in particular are most remarkable. Another circumstance which gives to this communication a still more interesting character, is the fact that Dr. Léon Danion, who for several years has endeavored to examine thoroughly this question of electro-therapy, has modified profoundly, in basing his investigations on physical and physiological grounds, the ordinary procedure adopted by others. He acted, nearly always, simply in the cavity of the uterine neck, and only utilizing intensities never exceeding sixty or sixty-five milliampères. He has, therefore, suppressed the higher intensities and the intra-uterine action; but he practises the reversing of the current, which appears to give to the treatment a considerable activity, as testified by the history of eleven patients whom he had treated in the wards of the eminent surgeon of the Hôpital Saint Louis, besides a number of cases treated by himself in private practice, and all of whom, with only one exception, whose case was complicated with rectal hemorrhages, have rapidly derived the most complete benefit which the treatment has till now given. Dr. Lucas-Championnière concluded his paper by recalling that he did not mean to attribute to the electric treatment of uterine fibromata and other uterine affections a primordial importance; but he wished to impress upon his hearers that, in the cases where the surgical treatment is not justified, it is the best of palliatives, and it succeeds particularly at the period of the menopause. He believes it to be not only unnecessary but positively dangerous to employ high intensities; one succeeds as well with the lower intensities, and there is no inconvenience to be dreaded. He himself never employs an intensity exceeding ninety milliampères. Moreover, he remarks that Dr. Apostoli believes the intra-uterine action indispensable, and thrusts the electrode into the uterine tissue when he cannot introduce it into the uterine cavity—a most condemnable practice. Dr. Lucas-Championnière believes that, in this latter case, one should be contented to apply it to the uterine neck. Finally, he reminded the meeting that Dr. Danion attaches a great importance to the reversing of the current; and he believes it to be advantageous to practise the operation with the speculum, after having thoroughly cleaned out the vaginal cavity.

Theophyllin—A New Constituent of Tea.—This new base, obtained from the alcoholic extract of tea, agrees in its elementary composition, $C_7H_8N_4O_2$, with that of theobromin and paraxanthin, but differs from both of these substances in its melting-point, mode of crystallization, and behavior with caustic soda. It gives no xanthin reaction, but on evaporation with chlorine-water leaves a scarlet red residue, which turns violet with ammonia, and is decolorized by excess of caustic soda. This body is described by Dr. Kossel, who discovered it as a dimethylxanthin.—*Therapeutic Gazette.*

To Cure a Black Eye.—There is nothing to compare with the tincture or a strong infusion of capsicum annuum mixed with an equal bulk of mucilage of gum arabic, and with the addition of a few drops of glycerin. This should be painted all over the surface with a camel's-hair pencil and allowed to dry on, a second or third coating being applied as soon as the first is dry. If done as soon as the injury is inflicted, this treatment will invariably prevent the blackening of the bruised tissue. The same remedy has no equal in rheumatic stiff neck.—*St. Louis Polyclinic.*

---

San Francisco has a Chinese physician, Li Po Tai, whose professional income is stated to be $6,000 per month. He has been established in that city for thirty years.

## INFECTION BY PHYSICIANS.

IN the *Centralblatt für Chirurgie* for September 28, 1889, Professor A. Neisser, of Breslau, discusses the question whether the physician who has been infected with syphilis should on that account limit his surgical and obstetrical activity. He cites the cases of four of his assistants who had acquired a finger-infection, and states that Fritsch had had eight assistants and six midwives similarly infected, all of whom continued their work. Other illustrations of infected persons and of transmission of syphilis by them are referred to.

Professor Neisser concludes that it is in the first two or three years of the disease only that there is any danger, and he believes that this danger is much lessened by active treatment.

He warns especially against the infected person doing obstetrical or surgical work with the specific eruption on his hands. A syphilitic person, also, who has a non-luetic eruption on the hand, should be extremely careful; furthermore, Neisser inclines to the belief that in the first year or two of syphilis the blood is infective, and that an accidental cut of the surgeon's hand would be dangerous.

However, with suitable precautions, the physician or surgeon who is infected can safely carry on his practice, and need hardly limit his work. The infected midwife is a much more dangerous person, for she usually has not the intelligence or honesty to recognize an affection if she have one.

A much more serious source of danger, in obstetrical practice particularly, is a puerperal fever of severe type. *The Northwestern Lancet* recently, in discussing this subject, recalls the classical case of Dr. Rutter, of Philadelphia.

In the year 1843 he had forty-five cases of puerperal fever in his practice, and in the next year twenty-five, while the other physicians of Philadelphia saw little or nothing of the disease. No amount of bathing, change of clothing, even shaving the head, had any effect. At last, in desperation, he went away from the city for ten days, and when he approached his next patient wore entirely new clothing and a new wig, leaving even watch and pencil-case at home. Yet this patient, too, was infected in the same way and died. Thirty years afterward Dr. Rutter's frightful record was explained by the disclosure of the fact that he was suffering at the time from a mucopurulent nasal catarrh, probably an ozæna.

A writer in *The London Lancet* describes two cases coming to his knowledge where medical men infected their puerperal patients through septic discharges from their own persons. In one case the source of infection was a slight but offensive discharge from the middle ear, the sufferer from which had a large midwifery practice with a great deal of septicæmia.

The other case was one of interest in connection with Neisser's article to which we have referred. It was that of an assistant who went to attend a case of childbirth in the absence of his principal. The woman died of puerperal fever, and investigation showed that the assistant was afflicted with tertiary syphilis and had an ozæna.

Such cases show us that physicians cannot be too careful of their persons when attending obstetrical as well as surgical cases.

## THE PATHOLOGY OF SCANDALS.

THE unsavory enterprise of the modern newspaper is constantly bringing to public notice instances of the weakness and sinfulness of human nature. The clergy, as a body, receive perhaps more than their share of notoriety, for if any ordinary man lapses a little it is thought to be something reasonably to be expected. A clergyman, however, who appears to have wandered from righteousness is the subject of the biggest kind of head-lines. It has been often said, among physicians, that strong religious feeling is usually united with a good deal of erotic fervor. This is, however, only measurably true. Religion appeals to the emotions, and successful preachers must cultivate perhaps unduly the emotional side of their character. The sexual feeling rises with the common emotional tide, but it is much less dominant than among artistic professions, where pure æsthetics is made the chief end of life and moral restraints are only secondary. The libertinism of the votaries of art in its various phases is a thing about which there is not much dispute, and it is amusing to learn that a certain prominent actor keeps a scrap-book containing a record of all the clerical scandals published in the daily press.

The practice of medicine tends to promote intellectuality and mental equipoise, so that medical history is rarely stained with records of misapplied confidence or scandalous violations of decency. Yet no one better than the physician knows how erring is human nature, and how full of temptations is the lot of any man who gains any degree of popularity or prominence. There exist in society a considerable number of men whose chief object in life is the gratification of lust, and who spend much of their time simply in devising ways of satisfying passion.

Such characters as Smollett's Count Fathom exist plentifully to-day, though modern novelists hardly venture to depict creatures so loathsome. These men are generally originally depraved; and modern alienists would place many of them among the moral imbeciles or paranoiacs.

But there are, unhappily, women of the same type; perhaps not so vicious, but much more weak. Large cities contain many of them, and they develop among the religious congregations as well as in the audiences of theatres. When one of them is struck with an erotic passion for her favorite clergyman, or actor, there is trouble ahead; and if the man is indiscreet or has enemies watching, a scandal surely follows. One basis for

scandals is insanely erotic women, therefore, and not necessarily bad men.

In justly estimating the merits of those cases involving the character of men who have lived lives without reproach, the pathological element of nymphomania ought to be considered. In some other cases the scandal is but the evidence of an incipient insanity, as in the case of a prominent lawyer who, in the early stages of paresis, went about making improper proposals to several of his respectable lady acquaintances. Scandal may be a sign of disease as well as of vice.

## THE WAY TO EDUCATE MEDICAL STUDENTS.

The continuous agitation by medical journals of the subject of the faults of medical education in this country has begun to bear some fruit. It is among the most significant results that the public begins to show a little interest in the matter. The daily press often treats of medical education editorially, and critical reviews publish articles about it. The *North American Review* has recently contained an article entitled "The Open Door of Quackery," written by three physicians well known as educators, Drs. Austin Flint and Eggleston, and Professor Doremus. In this article some plain statements are made regarding the deficiencies of American medical colleges. Dr. Eggleston, for example, says—and with perfect truth—"that there are not a dozen American medical colleges out of the one hundred and seventeen that would be tolerated for a moment in any foreign country that pretends to be civilized."

When the public generally knows that the above statement is correct, more care will be taken in selecting the family physician; and after a time it will, we trust, come about that intelligent people will not patronize medical men who have not had a thorough educational training, any more than they would hire an engineer who had not been carefully prepared for his profession, to build a difficult railroad, or to bridge a dangerous pass.

The two chief deficiencies in medical colleges just now are lack of the requirement of a good preliminary education and lack of facilities for clinical teaching and for technical instruction in the special branches. The latter requisite is being supplied measurably by post-graduate schools, and by the multiplication of small hospitals. The question of preliminary education is, however, often a serious one.

The physician needs to be not only a medical man with technical skill, but a man of some general culture and worldly knowledge. These latter elements are almost as important as the former. The worst way to make a physician is to take a youth of sixteen, put him at once into exclusively scientific studies, follow these up with medicine in all its branches, hospitals, laboratories, clinics, until by the time he is twenty-three he is a monument of technical knowledge. Such a course makes good operators in certain kinds of work; it produces a narrow specialistic skill, but not good general practitioners.

Preparatory schools of medicine are, we sincerely believe, useless and pernicious institutions.

The best preliminary training is undoubtedly such as is now given in our smaller colleges, but so modified in the last two years that the graduate in arts can graduate in medicine after two years of study in a medical college having nine months terms. Then, with a year or two spent in hospitals or post-graduate courses, the student is ready to do good work in his professsion, and he need not be more than twenty-four or five years of age.

## PROCURSIVE EPILEPSY.

A good deal has been written lately, in German and especially in French journals, about a peculiar form of epilepsy which is termed "procursive." Drs. Bourneville and Bricon have studied the disorder with great care, and have published a large monograph upon it (*Arch. de Neurol.*, vols. xiii., xiv., and xv., 1887 to 1888). Drs. A. Mairet and Ladame have also reported cases.

Procursive epilepsy is a form of epilepsy in which the patient does not have the ordinary convulsive attack, but instead of it suddenly runs forward, or in a circle. The attacks are usually brief, they are not ordinarily followed by somnolence or coma, and the patient does not fall.

Procursive epilepsy has been described by the older writers as *Chorea procursiva, seu festinans, s. rotatoria*, Systematized impulses, etc. No doubt the disease has often been looked upon as a form of hysteria or chorea.

Besides the true and typical procursive epilepsy there are cases of ordinary epilepsy with a procursive aura, so to speak. The patient suddenly runs forward, then stops, utters a scream, and falls into a convulsion. In other cases the running or rotatory movements follow the convulsive attack.

The cases of epileptic automatism in which the patient, instead of having clonic and tonic spasms, goes through certain familiar automatic movements, are very properly considered as belonging to this category.

In several cases in which autopsies have been made by Bourneville and Bricon, upon patients who had procursive epilepsy, an atrophy, more or less marked, of one of the cerebellar hemispheres, was observed, and it is believed that the forced movements are due to some involvement of this part of the brain. A case of Mairet's tends to confirm this view.

Procursive epilepsy is usually associated with organic brain defects, and it is, therefore, a particularly serious form of disease. Its treatment does not differ from that of other forms of epilepsy.

## IMPERFECT INTESTINAL ABSORPTION AND ITS MANAGEMENT.

Among the most certain and satisfactory of chemico-physiological tests is that of the absorption-rate of the intestines. This test was first described by Professor Ewald, in 1887, when he detailed a number of experiments which showed that salol was insoluble in the gastric juice, but that it was decomposed into its two constituents, when, after passing into the small intestine, it was subjected to the action of the duodenal contents. Very shortly after absorption into the circulation it passes through the kidneys, and is eliminated in the urine as salicyluric acid and sulpho-carbolic acid, its presence being demonstrated by the production of a red-violet precipitate when the urine, after acidulation with hydrochloric acid and shaking with ether, is tested with a solution of perchloride of iron.

Tests made by Ewald in 39 cases showed the presence of the reaction in the urine—

| | | | |
|---|---|---|---|
| After 30 minutes in | | | 1 case. |
| " 45 " | " | | 32 cases. |
| " 60 " | " | | 6 " |

Dr. Eccles (*The Practitioner*, October, 1889), repeated Ewald's experiments on fifty patients, and detected the salol components in the urine.

| | | | |
|---|---|---|---|
| After 25 minutes in | | | 3 cases. |
| " 30 " | " | | 2 " |
| " 45 " | " | | 42 " |
| " 60 " | " | | 3 " |

Thus it may be considered established that the average time required for salol to pass into the duodenum, be decomposed and pass through the kidneys is forty-five minutes.

Now in muscular weakness of the stomach, and in disease of the intestines, this time is greatly delayed, and by studying cases with the help of the salol test, the rate of improvement and the efficacy of remedies may be estimated.

Dr. Eccles has attempted to measure the value of abdominal massage in conditions of impaired digestion and absorption by the salol test.

In two cases in which the reaction was not obtained until an hour after injection of ten grains of salol (the amount always used in the test), abdominal massage was performed once daily for fifteen minutes for a week with no result. General massage was then done daily for forty-five minutes, for a week, when the salol was detected within half an hour after its ingestion.

Two cases of tropical diarrhœa and two of dilatation of the stomach were treated by general and abdominal massage daily. In one case treatment had to be abandoned, but in the other the rate of absorption, or gastric movements, which had been been abnormally slow, was brought nearly to normal, with corresponding improvement in the condition of the patients.

It may be considered proven that by vigorous and persevering massage intestinal absorption and the peristaltic activity of the stomach are improved. Whether this mode of treatment has a special value and reaches cases which could not be helped by other means, remains to be established.

## THE INFLUENCE OF HEREDITY IN THE CAUSATION OF TUBERCULOSIS OF BONE.

It is a matter of common observation that patients suffering from tuberculosis of the bones and joints, as well as those with the pulmonary form of the disease, not infrequently give a history of tuberculous troubles in the immediate family, especially in one or the other parent.

Some observations recently published by Dr. Julius Dollinger, of Budapest, in the *Centralblatt für Chirurgie*, No. 35, 1889, tend to confirm the belief in an hereditary predisposition which the general experience of practitioners has established.

Dr. Dollinger found, upon making inquiry of the parents or guardians of the children brought to him on account of bone or joint tuberculosis, that in a large proportion of cases one or more of the immediate ancestors had suffered from pulmonary phthisis. Usually, however, it was not the parents alone who were the sufferers, but the grandparents also, and not infrequently only he latter. The writer concludes, therefore, that bone phthisis occurs not in the children but in the grandchildren of those who have died from pulmonary tuberculosis. The influence of the tuberculous virus must be exerted through several generations before the normal resistance of the osseous structures is so far weakened that they become a suitable field for the lodgement and development of the tubercle bacillus. In other words, the author's experience adds weight to the common belief that the so-called scrofulous affections are a modified form of tuberculosis, and would seem to justify the retention of the term scrofula as expressing a mild, or at least a modified, form of the tuberculous disease.

# News of the Week.

MICROBIC EXPECTORATION STATISTICALLY STUDIED.—Böllinger has shown the curious fact that a cubic centimetre of phthisical sputum contains from eight hundred and ten thousand to nine hundred and sixty thousand tubercle bacilli. In other words, in an ordinary copious expectoration the consumptive deposits nearly a million bacilli in his cup, and in an ordinary day he throws thirty or forty millions of the micro-organisms out upon the cold world. The, at a low estimate, ten thousand tuberculous patients in New York City daily expectorate some 300,000,000,000 bacilli! The yearly number would be—but the imagination fails to follow such statistics. It takes at least eight hundred of the microbes, however, to start up tuberculosis even in a guinea-pig.

FIVE CHINESE LEPERS were shipped home from San Francisco, October 29th, on a Hong Kong steamer. Among them was a man who was sent to San Francisco from New York, where he had been employed as a cook for laborers on the Croton Aqueduct work.

A SEVERE INDICTMENT.—*Lanphear's Medical Index* says that Hot Springs, Ark., contains sixty practising physicians. Of these, seven are regular, and the rest thieves or quacks, or both.

ANOTHER OFFICE SNEAK THIEF.—Keep an eye on the man who leaves a message to call on a fictitious patient, and takes anything within his reach. Such an individual, who is well dressed, tall, thin, and dark-complexioned, is in the business. The best rule is never to allow any stranger to "wait for the doctor," unless he or she is under the eye of one of the servants. If this is impossible, have nothing in the waiting-room that anyone can steal.

MORPHINE-VASELINE AS A LOCAL APPLICATION IN CANCER.—In the *Asclepiad*, May, 1889, p. 147, Dr. Richardson states that morphine combined with vaseline forms one of the best possible sedative applications in cases of external malignant disease in which there is ulcerative breach of surface with continuous pain. The author prescribes it in the proportion of four grains of morphine to an ounce of vaseline, with two drachms of chloroform. The chloroform acts as a sedative, and causes the morphine to be better distributed. Morphine-vaseline is most conveniently applied thinly spread over a piece of fine lint or soft linen. It is easily removable without injury to the surface upon which it is applied, and should be renewed twice in the course of twenty-four hours.

THE LATE DR. ISAAC E. TAYLOR.—"The Faculty of the Bellevue Hospital Medical College have the painful duty of directing a record in their minutes of the death of their first and only President, the late Dr. Isaac E. Taylor. His invaluable services in the organization of the College, and his unflagging interest in its progress and success need not be recorded here. The same may be said of his contributions to medical science and of his labors in the various medical organizations of this City and State. His refined, gentle, and kindly nature endeared him to all, and especially to those associated with him in the Bellevue Hospital Medical College; while his lovable personal qualities protected him from the enmities which too often attend professional success.—AUSTIN FLINT, *Secretary.*"

At a meeting of the New York Obstetrical Society, held November 5th, the following preamble and resolution were unanimously adopted:

"*To the President of the New York Obstetrical Society:*

"Your Committee begs leave to present the following resolution, as in some manner expressive of the profound sense of loss felt by this Society in the death of Professor Isaac E. Taylor, M.D.:

"*Resolved*, That the members of this Society have learned with deep regret of the death of Dr. Isaac E. Taylor, one of its most distinguished Fellows. It is their wish to express here their high appreciation of his purity of character, his enthusiasm in promoting obstetric science, his lofty ideals, the kindness of his nature, his self-sacrificing disposition, and his warm-hearted benevolence. In recalling his life and character it is pleasant to remember that the deeds of good men live after them. —FORDYCE BARKER, M.D.; WILLIAM T. LUSK, M.D.; WILLIAM M. POLK, M.D., *Committee.*"

"The council of the New York State Medical Association sadly records its unfeigned sorrow for the loss of a valued Founder, Fellow, and late President, endeared by his personal qualities as he was admired for his scientific attainments. An illustrious name is transferred from the active list to the roll of honor of those who have bravely borne themselves in the foremost rank, and fallen triumphant. Untiring in industry, wise in council, affectionate in friendship, steadfast in religious faith, beloved by his associates, and revered by the profession which acknowledged him as one of its leaders, Isaac E. Taylor lived an example for emulation by his survivors and successors, and rests from his labor, leaving a reputation unassailed by enmity, and beyond the reach of jealousy. By the Council: JOHN G. ORTON, M.D., *President;* E. D. FERGUSON, M.D., *Secretary.*"

DR. BLANC, OF AIX LES BAINS, France, is paying a visit to this city, and is the recipient of many courtesies from representative medical men here. Numerous dinners, private and public, are tendered him, and he cannot fail to appreciate that his distinguished professional standing accords to him a becoming recognition.

TREATMENT OF SPRAINS.—It may be observed that a sprain is frequently treated with a liniment advised by physicians. It is indeed painful to see a physician writing a prescription for a sprain. There are but two indications in the treatment of sprains: 1, To provoke rapid absorption of the fluid effused around and within the joint; and 2, to favor cicatrization of the torn parts by immobilizing the articulation. Now, the modes of treatment hitherto in vogue do not fulfil these two indications. Massage would seem to present some real advantages, but it can be of little service in the case of severe sprains, and mild injuries would probably do as well under rest alone. An elastic bandage, the depressed parts being covered with a layer of cotton so as to prevent too great a pressure over the prominence, and thereby causing sloughs, will meet the first indication, and by its use in procuring rest it will meet the second indication. This bandage acts like massage in promoting absorption, and also secures immobility of the joint. It is of equal service in sprains complicated with rupture of points of insertion, whereas massage would be productive of harm in cases in which splinters of bone were torn away. The practice of relieving the mind of the patient by giving him something to do in the way of applying bad-smelling liniments is a pernicious one, and really shows an unprofessional or unscientific attendant.—*Canada Lancet.*

ANNIVERSARY MEETING OF THE NEW YORK ACADEMY OF MEDICINE.—The Anniversary Meeting of the New York Academy of Medicine will be held on Thursday, November 21, 1889. The address will be delivered by Dr. William M. Polk, entitled "The Relation of Medicine to Some of the Questions of the Day." This meeting is public, and the laity—ladies and gentlemen—are particularly invited.

PANPHOBIA.—Sanitarians will sometimes develop a certain degree of panphobia, and Dr. Baker, of the Michigan Board of Health, appears to have become a little touched with this affection. He has issued a circular, in which he states that the autumn fires in the woods and fields produce an amount of smoke which aggravates disease, causes sleeplessness, nervous disturbance, and general discomfort; and he adds that tonsillitis increased fifty per cent., and inflammation of the brain twenty-five per cent., in the month of October! Dr. Baker should live awhile in London, one of the healthiest cities in the world, but enwrapped most of the time in a cloud of smoke. It is sometimes wise to remember *Punch's* verse:

"Hygeia, thou'rt clever,
But, 'twixt you and me,
To fidget forever
Is fiddle-de-dee."

A SUBSCRIPTION has been started in Italy for the purpose of placing a marble bust of the late Professor Loreta in the hall of the University of Bologna.

DRESS OF MEDICAL STUDENTS.—The Council of the Senate of the University of Cambridge have recently had before them the grave question of the proper academic raiment of Bachelors of Medicine. In future the official attire of holders of that degree is to consist of a black gown of the same shape as the scarlet gown worn by Doctors of Medicine, and a hood like unto that worn by Masters of Arts, but lined with pink instead of white silk. It is to be hoped that this "purple and fine linen" will not turn the heads of the "new-made baccaleres" in medicine.

STILL ANOTHER NEW HYPNOTIC is "Somnol." It is an ethyl-chloral-urethane ($7H_{12}Cl_3O_3N$). It is given in doses of about thirty grains. It has been discovered by M. Radlauer, of Berlin.

A Sad Comment on Medical Non-Success comes from Chicago in the shape of the suicide of Dr. Edward Deans, at the age of seventy-one. He had been county physician of Cook County from 1860 to 1863, but decreasing practice and lack of means and old age induced the suicidal act.

Synthetic Somnambulism.—Dr. B. W. Richardson says that inhalation of the vapor of amylene produces a condition of somnambulism.

A New Lister Dressing.—It is stated that Sir Joseph Lister has devised a new form of surgical dressing and new antiseptic fluids, which are to surpass all his former achievements in this direction. He had intended to communicate a paper on the subject to the Congress of German Surgeons, but was not ready in time. It is now expected that he will describe his new methods at a meeting of the Medical Society early in November.—London Cor. *Occidental Medical Times.*

Electromania.—No other term can be applied to the condition of mind from which Dr. F. T. Paine, of Texas, seems to be suffering in connection with the use of electricity. This agent, according to the gentleman in question, relieves the pains of labor, stops the pains of crying children, produces a copious flow of milk from agalactic mammæ, and in general is a wonderful and universal anæsthetic. That electrical currents sometimes relieve pain and cause nervous sedation is a fact long well-known, but their power is limited and the promulgation of ideas like those of Dr. Paine simply bring disrepute upon our science.

The First Congress of Physiology, which was held at Basle last month, is spoken of as having been a model of what scientific gatherings should be, that is to say, it combined the maximum of work with the minimum of junketing and miscellaneous festivity. The idea of holding such a meeting emanated from England, and it was taken up both at home and abroad with as much enthusiasm as physiologists could be thought capable of. The task of organizing the Congress fell on Professor Miescher, of Basle, who spared no trouble to make it a success. The invitations were issued in January, and one hundred and twenty-nine physiologists responded to the appeal.—*London Medical Recorder.*

A Truly Woman's Hospital.—We learn that under the patronage of the Princess of Wales London is to have still one more hospital, which is, however, to differ very materially from those heretofore founded. Not only are all the patients to be women, but all the physicians, surgeons, and apothecaries connected with the establishment are to be of the softer sex.

Stricken with Apoplexy.—Dr. Bancroft, Sr., of Concord, N. H., formerly superintendent of the State Insane Asylum, was recently stricken with paralysis while conducting the meeting, in Boston, of the New England Psychological Society, of which he is president; toward its close he noticed that his left side was becoming gradually disabled. With a singular fortitude under the circumstances, he continued his duties as presiding officer, rising to make some concluding remarks, though leaning heavily against the table for support, and even putting the motion to adjourn after some of his associates had assisted him into his chair.

Cerebral Hyperæmia is a term much heard of some years ago, but it has of late been sinking into innocuous nosological desuetude, and in its place are learned articles about "congestive neurasthenia." Terminology fluctuates, but disease keeps about the same.

A Medical College in Connection with Cornell University.—President Adams, in his recent annual report, suggests that a medical department of Cornell University, located perhaps in New York City, would be a proper thing to have.

Vacancies Hard to Fill.—The Medical Examining Board for the Navy, which convened in this city last August, is still in session, and has so far failed to get any successful competitors for its examinations. There are nine vacancies to fill and there have been only four applicants, none of whom have been able to pass the examinations. It is stated that there has seldom been a time when applicants for the medical corps examination were so hard to obtain. It is nearly useless for a candidate to present himself before the board unless he can show his A.B. as well as his M.D. In other words, a candidate must have a thorough collegiate education, must be more than ordinarily proficient professionally, and must possess a good physique. As compared with other Government Services it is stated that last year ten vacancies existed in the medical corps of the Navy and five vacancies in the Marine Hospital Service. It was found well-nigh impossible to get candidates for the Navy medical examination, whereas there were about seventy-five applicants for the Marine Hospital Service. Candidates were afraid of the former examination and preferred to try one known to be easier. It is not an uncommon occurrence for two hundred candidates to present themselves before the army boards when there exist not more than two vacancies.

A Medical Journal Wins a Prize.—The *Riforma Medica*, a daily medical journal published at Naples, has just received the first prize in the section of medical publications at the Exhibition of Hygiene and Medicine recently held at Padua.

A New Ophthalmological Society has recently been established in Paris. M. Chevalerau is president, M. Chauvel vice-president, and M. Gorecki general secretary.

Is Man Left-legged?—Dr. W. K. Sibley read a paper before the British Association in which he argued that man was naturally left-legged. Standing working with the right hand, there was a tendency to balance on the left leg. Race paths were nearly always made for running in circles to the right, and the majority of movements (such as dancing, running, etc.) were more readily performed to the right. In walking, it was natural to bear to the right; crowds as well as individuals did so. Troops started off with the left foot; the left foot was placed in the stirrup or step of the bicycle in mounting; the left foot was the one from which a man took off in jumping. From measurements made by Dr. Garson of the skeletons of the two legs, in 54.3 per cent. the left leg was the longer, and in 35.8 the right. From measurements of 200 pairs of feet, it was found that in 44 per cent. the left, and in 21.5 the right, was longer, while in 34.5 they were equal.

# Society Reports.

## THE PRACTITIONERS' SOCIETY OF NEW YORK.

*Stated Meeting, November 1, 1889.*

FRANCIS P. KINNICUTT, M.D., PRESIDENT, IN THE CHAIR.

DR. ANDREW H. SMITH read a paper (see p. 541) entitled

### SACCHARIN AS A MEANS OF ACIDIFYING THE URINE.

DR. WEIR said that he had resorted to the use of saccharin in cases of alkaline urine about a year ago, and had since used it for this purpose a number of times. The results obtained were not always satisfactory, but usually he had been pleased with the action of the drug. He had obtained the best results in cases of vesical trouble following a gonorrhœa. Several years ago, Sir Henry Thompson recommended the use of pure lemon juice in cases of bladder trouble associated with alkaline urine. The speaker had tried it in several bad cases of prostatic cystitis, with very satisfactory results. The lemon juice was not always well borne by the stomach, but when it was the effect was generally very good.

DR. BEVERLEY ROBINSON asked whether the drug had any toxic properties. It had been asserted that it was sometimes productive of unpleasant effects.

DR. SMITH said that he had never seen any unpleasant effects from the drug, although he had used it quite extensively, and had also taken considerable quantities himself. He had not found that it caused any disturbance of digestion, but, on the contrary, it had seemed to act as a preventive of gastric acidity. A number of experiments had been made upon dogs, with the result of proving pretty conclusively that the digestion was in no way impaired by the administration of saccharin. Dujardin-Beaumetz had at one time thought that it was a toxic substance, but he had since, the speaker believed, asserted that the drug was harmless.

THE PRESIDENT asked whether the prompt effect of the drug were not due as much to its antiseptic action as to its acid properties.

DR. SMITH replied that that was a possible explanation of its beneficial effect in the cases referred to, yet saccharin was a powerful acid, and was not broken up in the body as were the vegetable acids.

DR. H. F. WALKER then read the paper of the evening (see p. 530), entitled

### TUBAL PREGNANCY TREATED BY FARADIC CURRENT.

DR. WEIR said that he had seen a case last spring in which the faradic current had been tried and had failed. Laparotomy was then performed, and the patient made a good recovery. The age of the fœtus was less than three months. He asked what result was to be looked for in these cases when no interference was attempted. Did not the fœtus often die of itself, recovery then following?

DR. CLEMENT CLEVELAND said that a German writer had recently collected reports of a number of cases in which the fœtus had died spontaneously. In one case the pregnancy had occurred fifty years before the death of the woman, the dead fœtus having been carried all that time without giving rise to any serious symptoms. The trouble in these cases is to make a diagnosis early enough to allow of proper treatment. The speaker had seen a case about two years ago, with Dr. Hawley, in which the patient complained of a good deal of pain, and examination revealed the presence of an abdominal tumor. They came to the conclusion that the case was one of extra-uterine pregnancy. Laparotomy was performed, and the mass was removed without rupture. On opening the sac, a fœtus, apparently somewhat over three months of age, was found. The woman made a good recovery.

DR. WALKER said that he did not regard it as safe to leave an extra-uterine pregnancy without interference, in the hope of spontaneous recovery. There were doubtless some cases in which recovery would take place, but it was not right to trust to this.

DR. WEIR asked whether the fœtus at this age could be killed by electricity employed in this way.

DR. CLEVELAND said that it was certainly a well-authenticated fact that electricity could destroy the fœtus.

DR. C. L. DANA said that he had been struck, in looking over the literature of electro-therapeutics, by the absence of any observations in which it was absolutely demonstrated that the electric current commonly employed for this purpose would kill the fœtus. A faradic current had doubtless often been employed on pregnant women without killing the child. If the fœtus could be killed by an ordinary faradic current, how easy it would be to produce abortion. Theoretically, it ought to take an alternating current of considerable strength to kill a fœtus in this way. So far as he knew, there had been no careful experiments made upon animals to determine whether these small currents really would kill.

DR. A. H. SMITH said that he had once killed a mouse very promptly by passing through its body the current from a faradic battery. He thought that a mouse would have as much power of resistance as a fœtus only two months of age, or even younger.

DR. CLEVELAND thought that the large number of cases in which electricity had been successfully employed for this purpose was sufficient to demonstrate its practical efficacy, despite the theoretical objections that might be raised against it.

DR. ROOSEVELT thought that the death of the fœtus might be due to stoppage of the heart by the direct action of the electric current.

DR. DANA said that he would admit the strength of the argument from experience, still he thought it was rather strange that there was no record of any experiments showing that the death of the fœtus could actually be brought about by the use of such mild electric currents.

DR. GEORGE L. PEABODY presented a specimen of the new hypnotic,

### CHLORALAMID,

and related his experience with it. He had been using it in Bellevue Hospital for about three weeks, in cases of insomnia of different kinds, from different causes and varying grades of severity, often complicating grave organic lesions. Chloralamid is formed by a chemical union between chloral and formamid. Of its manufacture little or nothing has been published, because the drug has been patented. It occurs in the shape of brilliant, white crystals, whose taste is slightly bitter. It melts at 115° C., and by distillation is resolved into its two components. It is very slowly soluble in ten parts of cold water, and in one and a half part of ninety-six per cent. alcohol. It is much more soluble in hot water than in cold, but care must be taken not to use water heated above 60° C., for the reason that a higher degree of heat causes it to become decomposed into chloral hydrate and formamid. This resolution occurs with great uniformity in the presence of alkalies, whereas weak acids do not affect it. It is probably decomposed by the alkali of the blood, and thus rendered potent as an hypnotic by the slow liberation of chloral.

The advantages claimed for this preparation are chiefly that respiration and heart-action are not affected by it: especially is blood-pressure lowered but little. According to our present experience with it, it does not disorder digestion. An effective dose is from thirty to forty-five grains. It should not be forgotten, in using chloralamid, that it contains over seventy-six per cent. of chloral, and therefore it should not be used in doses larger than sixty grains, or in daily amounts greater than one hundred and twenty grains. In its action it is a less energetic hypnotic than is chloral hydrate, and less prompt in the production of its effects. It requires from half an hour to an hour to make its influence felt.

In Dr. Peabody's experience, a headache the next morn

ing was of frequent occurrence following a dose of this drug; but he had never known the stomach or digestion to be disturbed by it. It has the advantage of being much less irritating to the mucous membrane than chloral. It can be well given in powder—being not deliquescent—or dissolved in wine or spirits. Its solution becomes easier if the vehicle is warmed. Its taste is less unpleasant than that of chloral hydrate.

Dr. Peabody had found it useful in all varieties of insomnia which are not accompanied by pain. In phthisis it had given good results in his hands; also in alcoholism, in fracture of the base of the skull, in intermittent fever, in typhoid fever, in phthisis complicated by alcoholism, in pneumonia, and in cerebral hemorrhage with very great restlessness. In two cases of neuralgia with insomnia it gave great relief. One of them was a pregnant woman with severe neuralgic pains in the thigh; the other was a case of multiple neuritis of alcoholic origin. It had never produced any alarming symptoms of any kind, and the only unpleasant one caused by it in his hands was headache. This headache usually passed off early in the forenoon. There is no such drowsiness the next day as there is after sulphonal, but it has not seemed quite as certain in its effects as the latter drug.

Dr. A. H. Smith said that he had made a trial of this drug at the Presbyterian Hospital the evening previous. The cases in which it was tried were suffering apparently from simple insomnia. The house-surgeon had reported that the result was not at all satisfactory. The action of the drug seemed to be that of diluted chloral merely.

Dr. Cleveland said that he had tried it in one case, that of a lady who had been taking sulphonal for some time, and to whom he thought it desirable to give some other hypnotic for a while. The effect was very unsatisfactory. His patient said that the drug had failed to give her sleep, but rather caused excitement, and she also complained of headache. He had had to return to the sulphonal.

Dr. Beverley Robinson reported a case of

INTESTINAL HEMORRHAGE

occurring in a patient at St. Luke's Hospital. For the notes of this case he was indebted to the house-physician, Dr. William H. Caswell. The patient was a married woman, aged twenty-three, who was admitted to the hospital on October 27, 1889. She gave a previous history of languor and anorexia for one week or more, followed by a rise of temperature from 102° F. to 105° F. There had been persistent vomiting of the milk and lime-water which had been ordered as the sole diet. There had been no blood in the vomited matters. On admission the patient was able to talk intelligently, she had a pulse of about 90, a white-coated tongue, tympanites, and some tenderness on palpation over the abdomen. The vomiting continued, and toward evening on the day of admission began to show some blood mixed with the partially digested milk. The hæmatemesis continued through the night, about two or three ounces being vomited at a time. The bowels moved voluntarily four times during the night and early morning, the motions being loose, of a light yellow color, and unmixed with blood. The patient died about noon the day after admission. A diagnosis had been made of typhoid fever with intestinal hemorrhage, and after death a needle inserted into the left side of the abdomen, as nearly as could be determined into the lower part of the descending colon, showed the presence of dark-colored blood rather thick in consistency, though fluid. No autopsy was allowed. The case was interesting from the fact that no blood escaped from the bowel, but was vomited.

The President said that he had known of a case within the last ten days, occurring in the person of a physician, in which the symptoms were typical of typhoid fever. The patient died from hemorrhage. A large quantity of blood was vomited, but none passed from the anus.

The Society then adjourned.

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, October 24, 1889.*

J. E. Janvrin, M.D., Chairman.

Dr. R. A. Murray read a paper on

THE MANAGEMENT OF ABORTION.

He had become convinced from observation that no fixed rules guided the general practitioner in the management of abortion; that the treatment was too frequently wavering, hesitating, a waiting on nature. While the application of antiseptic principles had been brilliantly successful in labor at full term, it had been greatly neglected in early delivery or abortion. It should be borne in mind that abortion, using the term to mean expulsion of the product of conception before viability, was always a pathological process.

In the early weeks the abortion was usually accomplished quickly, without very profuse hemorrhage, the deciduous membrane coming away with or after the ovum. The expulsion was not so much from uterine contraction as from hemorrhage into the uterus. At the middle of the second month the deciduous membrane was more firmly attached and likely to remain, causing hemorrhage. After this period the conditions were different; the placenta having fully formed the miscarriage could be divided into two stages: 1, The separation and expulsion of the fœtus; 2, the separation and expulsion of the afterbirth. Here hemorrhage was not usually an important factor before the expulsion of the ovum, unless traumatism were the cause. The contractions determined the expulsion, and as they were inefficient the case proceeded slowly. The hemorrhage taking place after expulsion of the fœtus usually ceased after a short time, to come on more profusely afterward. The placenta was often detached piecemeal. Hemorrhage was always present in abortion, was likely to be profuse, was always so when the expulsion was in two parts, the ovum first, then the membrane. It generally preceded as well as accompanied expulsion of the ovum, and its continuance was almost positive proof that the membrane or placenta had been retained.

The treatment of abortion was discussed under the headings prophylaxis or curative measures, and the management of complete or incomplete abortion. By prophylaxis was understood the treatment of the various constitutional and diasthetic causes which operated to produce miscarriage, such as syphilis, lead-poisoning, uræmia, profound anæmia; also local conditions, as changes in the uterus; traumatic influences, as heavy lifting, etc., which caused congestion of the uterus.

When abortion was threatened, shown by pain and hemorrhage, the patient should take the recumbent position, cool drinks be given, moral disturbances be avoided. For pain, administer opium in full doses. Drachm doses of compound extract of viburnum every two or three hours, until the pain and hemorrhage had ceased, had been useful. Chloral hydrate and bromide of potassium, by stopping pain and relieving nervous excitement, had contributed to allay uterine action.

If the symptoms continued, the cervix softened, there was tenderness in the uterus and ligaments, particularly if there had been an escape of the waters or any part of the uterine contents, we were warranted in ceasing our efforts at prevention and in hastening the abortion.

All examinations should be made with strict antiseptic precautions. If the hemorrhage were not profuse and the cervix not dilated, an injection of a solution of carbolic acid might be made, and an antiseptic pad applied to the vulva. To hasten the abortion a vaginal tampon was introduced of iodoformized or borated cotton, closely packed around the cervix by the aid of an applicator used through a speculum, the patient being in Sims' position. Where the hemorrhage was profuse alum might be used, but it was objectionable in that it contracted the

vagina. It possessed the advantage, however, of checking hemorrhage or damming the blood back in the uterus, causing the cervix to distend and enhancing uterine pains. If not left in more than twelve hours it remained antiseptic, and was to be preferred to the colpeurynter. Ergot might be given in moderate doses; large ones caused rigidity of the cervix and retarded expulsion. If, when the tampon was removed, the os was dilated, the ovum could usually be reached by the finger, in which case it was best to proceed to empty the uterus. Thorough exploration of the endometrium was facilitated by pressing the fundus downward and forward with the other hand over the abdomen; if the products of conception could be detached by the finger, it should be removed by a placental forceps passed up alongside the finger, grasping the loosened structure, twisting it around, and withdrawing it. If any portion remained it should be scraped off with the blunt Thomas curette; the operator should not be satisfied until the whole endometrium was smooth. The uterus should then be washed out with carbolized water, preferably through a double catheter, and the one he used most was Fitsch's, with a somewhat smaller curve than the original. The current continued to flow as the tube was withdrawn, membranes were washed from the uterus and vagina, and a pad then applied to the vulva. Hemorrhage would cease entirely on completely emptying the uterus. He had not had occasion to repeat the uterine injection; there had been no febrile or septic symptoms, no pelvic peritonitis. If the single catheter were employed, care should be taken that there was perfect egress of the fluid. If the uterus had been depressed in the way mentioned, one must not forget to lift it by the finger to the normal position. No antiseptic, as iodoform, should be used in the dressings which would obscure the odor should decomposition afterward take place. Nor did he ever use bichloride of mercury unless the products removed were already decomposed; in that event he employed 1 to 5,000, leaving none of the injection in the uterus. Such was the course he pursued when he had seen the case from the beginning.

In incomplete abortion the patient might give one of two histories: 1, The products of conception having passed, but not saved for inspection; 2, presence of pain and hemorrhage, no knowledge of escape of the ovum, although it might have taken place with the bloody discharge.

If the abortion were incomplete and the cervical canal closed, what course should be pursued? This had been a mooted question. Many authorities were in favor of emptying the uterus at once; others, especially the French, advised the expectant plan. The author thought that if the uterus was still large and the cervix soft, though but slightly open, it would be far safer, although hemorrhage may have ceased, to carefully introduce the blunt curette or small uterine sound and gently explore for inequalities of the endometrium; if found, to dilate, remove the remains, and use the douche. In neglected incomplete abortion, with fetid lochia, retained placenta, intermittent hemorrhage, septic absorption, the canal should be dilated, the cavity thoroughly washed by an antiseptic solution, the blunt or sharp curette used, this followed by another intrauterine and vaginal douche, the vaginal douche to be repeated if the fetor continued in the lochia. Such remedies as alcoholic stimulants, digitalis, and quinine might be called for. The author also discussed briefly the use of galvanism and faradism for exciting uterine contractions. He doubted their value, although he had had no personal experience with them. He thought the curette was superior to the use of the brush, or what was called *grattage* by the French.

There was a large mortality from puerperal diseases, due in considerable measure to neglected cases of abortion. This would cease if physicians generally would observe the simple rules described in the paper.

Dr. A. F. Currier thought the treatment of abortion was one thing in regard to which the profession had reached a certain degree of exactness, and it was largely due to advances made in antiseptics. There was little to criticise in the paper. He thought, however, that uterine contractions had more to do with early abortion than the author had stated. He laid stress on the use of the blunt curette in diagnosis, particularly as to the condition of the endometrium after the fœtus had been expelled; it was superior to the finger. After cleaning out the uterine cavity, he applied to its surface pure carbolic acid. He knew of but one exception to the course of treatment by the use of the curette, etc. It was in a class of cases like one he saw last summer, in which the patient, seen in consultation, had become almost moribund from loss of blood and exhaustion. She was extremely anxious to have a child, and for that reason her physician had not hastened abortion. When Dr. Currier saw her they tamponed the vagina; in a few hours the fœtus came away, and, as far as he could determine, all the membranes. Because of this fact and that of her exhausted condition, he did not curette the uterus. She died in about forty-eight hours. In addition to tamponing the vagina, spoken of by the author, he thought it important also to insert a plug into the uterus.

Dr. P. F. Mundé referred to a paper which he published in 1883, taking positive ground regarding the immediate removal of the secundines, and it elicited a good deal of criticism. Speaking now of early incomplete abortion, he would take equally positive ground; seeing that the fœtus could not be saved, he would endeavor to spare the woman all the blood possible by hastening dilatation. That he would bring about by tightly tamponing the vagina with iodoform gauze so that there could be no escape of blood. The gauze could be removed in twenty-four hours and replaced if necessary. That was not always sufficient. It was sometimes necessary to dilate the external os and rapidly complete the abortion, in which case he would use a tupelo tent. Being able to introduce one or two fingers, he would endeavor to remove the contents of the uterus in tact. This, however, could seldom be done, for the consultant rarely saw a case of abortion in its incipiency, or before the fœtus had escaped.

The class of cases which he usually saw was those in which there was hemorrhage or septicæmia, and the canal was usually large enough to admit the finger; if not, it could easily be opened. He then curetted with the blunt curette, or, if necessary, Carl Braun's curette. He had long taken the ground that a woman who had incompletely aborted was liable to one of two serious accidents, namely, hemorrhage, which might be fatal, or septicæmia. Consequently he contended that, notwithstanding some physicians had seen many cases in which nature had saved the woman, yet none should be allowed to linger and take such grave risks. Having curetted, he introduced a forceps and brought down the membranes, then reintroduced the finger to see that the endometrium was smooth. He washed out the uterus with hot water through a double catheter; never employing corrosive sublimate, through fear of poisoning. Out of some hundred cases he had lost only one, and in that instance he believed the pelvic peritonitis was due to sepsis developing before the commencement of treatment.

Dr. Fry, of Washington, had been especially interested in the advice to use antiseptic injections. Regarding viburnum, he had not been able to satisfy himself that it did any good. The tampon he used very little, or only a very short time, believing it to be better to employ a dilator. Tents were objectionable; even the laminaria had been found to contain micro-organisms after a few hours presence in the cervical canal. He preferred applications of equal parts of creosote and iodine to carbolic acid, as the action of the latter on the lining membrane was very superficial. Dr. Grandin had suggested that he give his experience with electricity. He had made some experiment in this direction. The faradic current was used only with a view to increase the uterine contractions when present, not to provoke them in the first place. He had also made some experiments with the galvanic current to

test the coagulating effect of the acid from the positive pole as a means of cutting off the blood-supply of the membranes and thus bringing about their expulsion; this pole was also known to eliminate oxygen and chlorine, which were powerful antiseptics. His experiments had not been completed.

DR. MALCOLM MCLEAN had found that the cotton swab would often pick up shreds on the uterine walls which the curette and other instruments would fail to bring away. Shreds of considerable size sometimes came away on the cotton swab wrung out of ninety per cent. carbolic acid. He further spoke of valuable service derived from Emmet's curetting forceps.

DR. H. J. BOLDT thought the pad from a three per cent. solution of carbolic acid was not sufficiently antiseptic; the bichloride pad was better. He thought the finger was far superior to the curette in making a uterine examination, and ought always to be given the preference. He did not approve of the use of so much force in removing the membranes as was implied in the recommendation of some instruments. Better leave such pieces of membrane to be dislodged by time.

DR. COLLYER could not understand how, during the early weeks after the third month, one could remove all the secundines without the sharp curette; the finger or blunt curette would not answer. He said that as soon as hemorrhage occurred it would be impossible to stop the miscarriage; therefore he forcibly dilated the cervix and curetted with the sharp curette, then used a cotton swab dipped in a solution of bichloride, followed by tincture of iodine on a cotton applicator, and finally a vaginal tampon of antiseptic wads. That was up to the third month. After that period he employed open drainage or packed the endometrium with iodoform gauze. He used bichloride injections. He added that if peritonitis developed he applied ice-bags.

DR. MUNDÉ remarked that he had often been called to women who had lost some blood by threatened abortion, the abortion, however, not becoming complete.

DR. E. H. GRANDIN wished to place himself decidedly in opposition to the sharp curette, either after miscarriage, abortion, or labor at full term. Traumatism, which was liable to follow its use in the puerperal uterus, must be strictly avoided.

DR. KEARNEY gave some experience, apparently showing the necessity for the sharp curette in certain cases. He also related two cases in which there was retroflexion with fixation, due seemingly to perimetritis; but the injection of hot water in one caused the uterus to spring suddenly back and become anteflexed, showing, as was shown by the post-mortem examination in the other, that perimetritis did not exist.

Dr. Murray closed the discussion.

DR. H. C. COE then read the history of a case (see p. 478) of

RUPTURED UTERUS AT TERM; HYSTERECTOMY.

DR. A. P. DUDLEY related a case of

EPITHELIOMA OF THE OVARIES AND UTERUS; EXTIRPATION.

The patient was an Irishwoman, aged fifty-one, mother of three children, had been in hospital about a year before she returned to him to have something radical done for her relief. There were no objective symptoms of malignant disease, the physical signs were those of uterine fibroids, and he opened the abdomen with a view to doing suprapubic hysterectomy. He removed the ovaries, tubes, and uterus, in the manner which he designated the intrapelvic but extraperitoneal method of treating the stump. When the operation was completed it left a row of sutures extending down the broad ligament on one side, across over the stump through the peritoneum, and up the broad ligament on the opposite side, while the stump, consisting of the vaginal portion of the neck, lay beneath. About the third or fourth day a little rise of temperature was likely to take place, when he inserted a drain up through the cervix, and the patient then went on to recovery. He had so operated about five times, all the patients recovering. The pathologist leaned to the diagnosis in this case of epithelioma of the ovaries and uterus.

DR. GOFFE had performed this operation successfully, and thought well of it.

THE CHAIRMAN suggested inserting a drain before the rise of temperature took place, indicating the formation of pus.

## Correspondence.

### A PLEA FOR THE MASSEUR SERIOUSLY CONSIDERED.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: THE RECORD of October 26th issues a word of warning against the masseur, who "is bearing down upon unhinged humanity with a steady and relentless stride," and who, instead of losing heart on account of increased competition, "simply enlarges his field."

The writer has had the audacity, though only a layman, to engage in medical gymnastics and massage as a profession, but hopes that you, notwithstanding this, will allow him to say a few words on the subject.

Massage and medical gymnastics are practised by a great many in this city, the majority of whom are qualified for it neither by congenital intellect nor by acquired education. They are practised by totally uneducated persons partly on their own responsibility, partly and, I must confess, largely on the recommendation of physicians. If this is an evil, and everyone who has only a little sprinkling of common-sense admits it to be, who is to blame for it? Is it the public at large, who read the advertisements of "schools," "colleges," and "bureaus of massage" in the Medical Register and the medical journals, and who know their medical adviser to prescribe massage, many times allowing the patient to send for the "rubber doctor" around the corner, because he is cheapest? Certainly not. Or are the men and women, trained or untrained nurses, to blame, who when tending a patient are told by the physician to "rub" the paralyzed limb, to "press" the painful nerve, or to "knead" the constipated bowels? Is there any wonder that these persons think it a very easy way to make money, that they know it all, and that they are full-fledged "rubbers?" Certainly not; this is only natural and to be expected. The blame falls exclusively, or nearly exclusively, on the doctor who, when prescribing massage, or "Swedish movements," recommends no operator at all, or one who has not proven himself to be thoroughly versed in both the theory and practice of his business. It falls on the physician who, himself knowing practically nothing about this treatment, recommends the first man who comes to his office presenting a tolerable respectability in dress and manners. That physician is also to blame who calls in a good masseur or gymnast, but advises the patient to have a servant to look on a few times, afterward to go and do likewise; and also on him who considers himself in learning and social standing so far above these laymen that he does not deign to talk or (I dare say it, though I imagine I hear the sneer!) consult with the man engaged upon his recommendation. If he did so, he would soon find, even in this profession, men his equals in education and learning even if they never studied materia medica. He would also find men whose ignorance in the rudiments of their own science would show itself so plainly already at the first conversation, that the physician should be very glad to shun them in the future.

You also complain that the field of massage of late has become so enlarged. The masseur claims to be able to accomplish very much! Well, yes! But a great part of this enlargement is legitimate. The skilful gymnast or masseur can really accomplish more nowadays

than twenty-five years ago, just as the physician can. But though I have seen men claim by massage to press the adipose tissue out through the pores, or by magnetic action to take the patient's ailments in their own bodies, and other things equally easy for them, I never yet heard of massage of the heart, which you mention! But do you mean general massage and systematic gymnastics in cardiac diseases?—if so this is certainly nothing worth sneering at. The benefit from this is perhaps greater than from Oertel's method, and it would perhaps not be totally out of place for physicians to consider if this treatment in many cases of atrophied, hyperrophied, or fatty heart be not indicated.

And when the intelligent mechano-therapist gets a case from a physician (and, as a rule, he takes no cases which have not passed through the hands of an M.D.) he asks for the history and the diagnosis, and then gives his opinion whether he can do everything, anything, or nothing, and his reasons for the opinion. If this opinion, perhaps afterward, is found to be erroneous, what more! This happens to us all, and cannot be helped.

This letter may look as a defence against the attack made by you on masseurs, but that is by no means my intention: hit harder, if you please! Nobody will enjoy it better than the able men in that profession. I join also in your warning: "Keep a close eye on the masseur;" but keep also a close eye on the massage to detect what can really be accomplished by it, in order not to throw out the child as well as the bathing-water.

Very respectfully,
M. G.

NEW YORK.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 3 to November 9, 1889.*

O'REILLY, ROBERT M., Major and Surgeon. By direction of the Secretary of War will, at the expiration of his present leave of absence, proceed to Fort Logan, Col., and report in person to the commanding officer of that post for duty. Par. 6, S. O. 256, A. G. O., November 2, 1889.

MERRILL, JAMES C., Captain and Assistant Surgeon. Relieved from duty at Frankford Arsenal, Pa., and ordered to duty at Fort Reno, Ind. Ter. Par. 6, S. O. 256, A. G. O., November 2, 1889.

BLACK, CHARLES S., Captain and Assistant Surgeon. Relieved from duty at Fort Sidney, Neb., to take effect upon the expiration of his present leave of absence, and to report in person to the commanding officer, Fort Du Chesne, Utah. Par. 6, S. O. 256, A. G. O., Washington, November 2, 1889.

POWELL, JUNIUS L., Captain and Assistant Surgeon. By direction of the Secretary of War, leave of absence for two months on account of sickness, with permission to leave the Division of the Missouri, is granted him. Par. 2, S. O. 258, A. G. O., Washington, November 5, 1889.

JOHNSON, R. W., Captain and Assistant Surgeon. Leave of absence for one month is granted, to take effect on or about November 10th. Par. 4, S. O. 110, Department of Arizona, Los Angeles, Cal., October 29, 1889.

IVES, F. J., First Lieutenant and Assistant Surgeon. Granted two months' leave of absence. Par. 3, S. O. 256, A. G. O., November 2, 1889.

WILLCOX, CHARLES, First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, to report to the commanding officer at Fort Columbus, N. Y., for duty at that station.

MCVAY, HARLAN E., First Lieutenant and Assistant Surgeon now at Fort Mackinac, Mich. By direction of the Secretary of War, to report in person to commanding officer at that post for duty.

FRICK, EUCLID B., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, to proceed from Philadelphia, Pa., to Fort Keogh, Mon., for duty at that station.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 9, 1889.*

MACKIE, B. F., Surgeon. Detached from the U. S. S. Ossipee, and placed on waiting orders.

PICKRELL, GEORGE MCC., Assistant Surgeon. Detached from the U. S. S. Ossipee, and placed on waiting orders.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 9, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 35 | 8 |
| Scarlet fever | 47 | 2 |
| Cerebro-spinal meningitis | 4 | 4 |
| Measles | 41 | 4 |
| Diphtheria | 91 | 15 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

THE STOMACH-BRUSH.—A dental journal publishes the following, translated from the German: In 1713 there was published a pamphlet entitled, "A Complete Account of the most Useful Stomach Brush which is now to be had at the Brushmakers at the Old Court Sadler's Shop in Broad Street in Colln-on-the Spree." Many a one may have wished to be able once in a way to have his stomach thoroughly cleaned out, and this speculative brushmaker gave a practicable means to give effect to this wish. In the pamphlet there is a drawing of the stomach-brush; it resembles a pipe-cleaner, but, of course, is larger. The stalk is made of four wires twisted together, covered with thread, silk, or small ribbons; it is twenty-six inches long. The brush at the under end is two inches long and one and a half broad, and is made of goat's beard hair; but, when one has been accustomed to use it for three or four weeks, a horse-hair brush is substituted, this hair being somewhat stronger, and so the effect is better. The application of this most excellent brush is very simple. It is pressed through the throat down into the stomach, which, by drawing up and down of the brush, is cleaned; thereafter cold water or brandy is to be drunk, and the operation is repeated till the cleaning is perfect. The cure is to be repeated every morning. The author says: "At first you will find it rather troublesome to get the brush down, but when you put it in your mouth and on your palate, draw in breath and wind, and press it gently and gradually down, and, without any particular trouble, it will reach the stomach. After eight to fourteen days' practice, it will come as easily to you as eating or drinking." Of course, the daily application of the stomach-brush is the infallible remedy or preventive of all diseases that can be imagined. "Whoever uses this cure requires no other medicine, for it is good against all—cold, hot, and poisonous fevers, it gives a good appetite for eating, it is good against asthma, hemorrhage, headache, chest complaints, coughs, consumptions, apoplexy, toothache, sore eyes, dysentery,

quinsy on the tongue, quinsy in the throat, ulcers, abscesses, cardialgy; it favors digestion, strengthens the heart, drives away pimples on the skin, is against choking in the stomach, etc., makes too fat and asthmatical and swollen-up people thin, and, on the other hand, makes meagre and thin people fat. The great effect, however, is produced only when the use of the brush is combined with that of an elixir. This is compounded of aloes, saffron, rhubarbona, lark-mushroom, wormseed, eugian, myrrh, theriac. After the stomach-washing, forty to fifty drops of the elixir is to be taken in wine, and this preserves for twenty-four hours against all poison and pestilence."—*British Medical Journal.*

Disease-Ridden Indians.—Indian Agent Jones, of the Berthold Agency, has made application to the Department for a physician who shall remain constantly at the Agency. This request is the result of hurried examination of the health of the Indians. Mr. Jones was recently appointed. He finds that disease runs rampant among the entire Indian community. The Indians at this Agency are in a most deplorable condition. In the past their health has been neglected, they have been permitted to roam about the country and, as a result, some members of the tribe have returned to their camps laden with disease, which has spread to nearly every Indian at the Agency. It is understood that the request for a physician has been granted, and that steps will be taken to prevent the further spread of disease among the tribes. The condition of affairs at the Agency in the past has not only ruined the health of the Indians, but has been a constant menace to the whites with whom the Indians necessarily associated. So great became this danger that the county and city authorities were alarmed, and the Mayor of Bismarck was compelled to serve notice on the former agent that if he did not keep his Indians on the reservation an investigation of the matter would be demanded.—*The Journal of the American Medical Association.*

An Artificial Laryngeal Pouch.—One of the duties of the army surgeon is to "spot" the professional malingerer, whose wiles occasionally testify to the possession of an amount of cunning and technical skill which, in civil life, might prove highly remunerative if judiciously applied. Our "lobsters," however, are mere bumpkins compared to the artful Hindoo, who, "for ways that are dark," can give him points in abundance. The professional thief in India experiences a great deal of difficulty in finding a safe receptacle for his plunder, and it has been recently discovered that many of them are in the habit of bringing about the formation of a pouch-like recess in the vicinity of the epiglottis, by allowing a leaden ball to rest *in situ* for long periods of time. When repeated at frequent intervals a pouch is formed, capable, in some instances, of holding as many as ten florins or an equivalent bulk of jewels without any obvious interference with respiration or speech. An examination of the prisoners at Calcutta revealed the fact that upward of twenty of them were provided with this convenient pouch.—*The Hospital Gazette.*

Psychical and Physical Changes Following Removal of the Ovaries.—In an elaborate study of this subject by Dr. Glaevecke (*Archiv. f. Gyn.*, Bd. xxxv., Heft 1), the author says: "After removal of the ovaries, menstruation ceases permanently in eighty-eight per cent. of the cases, either at once, or after a certain interval, while in the other twelve per cent. the flow becomes scanty and irregular. Vicarious hemorrhages are rare. In one-half of the cases observed the menstrual molimen persisted after the cessation of the flow. The usual climacteric phenomena, vertigo, irregular sweating, leucorrhœa, etc., are common, as well as the atrophy of the genital organs which follows the establishment of the menopause. Even when the uterus is considerably enlarged, by reason of the presence of chronic endometritis or fibroids, it commonly returns to its normal size after oöphorectomy, or even becomes atrophied. The general condition usually improves after castration;" in forty-two per cent. of his case the patient became stouter. Sexual desire was dimins ished in the majority of the cases; in some instances it was extinguished. The physical disturbances were most marked, sometimes amounting to melancholia. "In short," says the writer, "removal of the ovaries induces an artificial menopause which is exactly similar to the natural one."

African Jumpers.—Dr. Bennett, of Griqualand, writes in the *South African Journal* an account of a peculiar nervous affection which is met with among the Griquas and other natives and individuals of mixed descent living in Griqualand. He suggests that perhaps the affection is similar to that prevalent among the French Canadians, and known there by the name of "Jumpers." Dr. Bennett says: "The affection is entirely confined to the male sex, and I have never seen or heard of a case in the female. The victims of this strange form of neurosis go through the most extraordinary and grotesque antics on the slightest provocation. A whistle, a touch, a shout—anything, in fact, sudden and unexpected, will 'set them going.' Some will stiffen their limbs, make hideous grimaces, and valse about as if they had no joints in their body. Others will jump wildly about like dancing dervishes, imitating the particular sound that had acted as an exciting cause. Some, again, will make use of the most obscene expressions on a transient impulse, correcting themselves immediately afterward, and expressing their regret for having used such language, while others, on the spur of the moment, will do anything they are told to do. If they should happen to have a piece of tobacco in their hand, and one should suddenly shout, 'Throw it away!' they will do so at once, running away for a short distance, and trembling all over their body. I remember one case in particular; it was that of a 'Bastard' boy, a mason by trade. He had been handed a piece of tobacco, and the person who handed it to him shouted out suddenly, 'Throw it away; it is a snake!' He first danced about wildly for a short time, and then ran away as fast as he was able; but he had not gone far when he fell down in a 'fit,' and it was some time before he recovered." As to the probable cause of this affection, Dr. Bennett is disposed to ascribe it to the indiscriminate intermingling of the blood of different racial types, and the intermarriage of those standing in close relationship to one another.

Treatment of Dandruff.—The following suggestions are sent by correspondents of the *British Medical Journal*. P. M. S. suggests the following ointment to be applied to the roots of the hair every night for a fortnight or so. ℞. Ung. hydrarg. nitr., ʒ j.; vaseline, ʒ vij. The hair to be cut short and well brushed every morning. R. T. suggests the following ointment, used as a pomade: Red oxide of mercury, ammoniated mercury, of each ten grains; spermaceti ointment, an ounce. Dr. H. Laird Pearson writes: "Personal experience enables me to recommend the following: ℞. Hydrarg. perchlor., ʒ ss.; glycerine, ʒ v.; eau de Cologne., ʒ v.; aq. ad ʒ xx. M. Ft. Lotio No. 1. ℞. β naphthol, ʒ ij.; alcohol. ethylic., ʒ xx. M. Ft. Lotio No. 2. ℞. Acid. salicyl., ʒ ij.; tr. benzoin co., ʒ jss.; ol. olivæ ad ʒ x. M. Ft. applicatio. Wash the head thoroughly with terebene soap; rinse well and dry with a rough towel; rub in some of the No. 1 lotion and dry with a towel; next apply lotion No. 2, and allow it to evaporate off; finally rub in thoroughly a small quantity of the oily application. The treatment should be carried out daily for a month, and then every alternate day for a fortnight. The dandruff disappears in a few days, and the hair becomes vigorous and supple in a remarkably short time." E. Mansel Sympson, M.B., writes: "I have used the accompanying formula with very good results, both in simple alopecia, and that attended by, or perhaps rather caused by, dandruff. ℞. Tr. cantharidis, ac. acet. dil. āā ʒ ss.; sp. rosmarini, ʒ j.; glycerin., ʒ ss., aq. rosæ dulc. ad ʒ viij. Ft. lotio. Let this be well

rubbed into the roots of the hair with a small sponge or a flannel, and let special care be taken not to wash the head, for, as far as I have seen, washing only aggravates the evil. Good brushing and combing should be quite sufficient to keep the hair clean. The formula given above is slightly altered from one of the late Mr. George Nayler's."

THE PARASITIC NATURE OF PAGET'S DISEASE OF THE NIPPLE.—It is well known how intractable this affection is, and how often, indeed almost invariably, it leads to the development of cancer. Various theories as to its nature have been propounded by Butlin, Thin, Dühring, and others, some supposing it to be eczema of the nipple spreading into the galactophorous ducts, others a disease *sui generis*. Dr. J. Darier now claims to have proved that it is parasitic in character. If epidermic scales are taken from the diseased surface and treated with dilute ammonia or bichromate of ammonia, round bodies surrounded by a refracting membrane will be seen among the epithelial cells, and frequently within them. These bodies have a diameter equal or superior to that of the cells; their investing membrane contains a single mass of protoplasm, or more or less numerous corpuscles. These bodies are certainly coccidia. In epithelioma of the nipple the granulations contain similar parasites. M. Darier suggests that this discovery may be the first step toward the elucidation of the nature and mode of origin of some epitheliomata.—*Medical Recorder.*

INHALATIONS OF COLD AIR IN HÆMOPTYSIS.—Dr. P. de Tullio, assistant to Professor Cantani in the University Clinique at Naples, has lately suggested a method of applying cold air directly to the interior of the lungs in cases of pulmonary hemorrhage. The apparatus consists of a metal box through which run several tubes, which communicate with an outer larger tube leading to a mouthpiece, which the patient holds between his lips. The box is filled with ice, or with a mixture of snow and salt, so as to cover the tubes. Air is then pumped with a suitable bellows into the tubes, and in its passage through the box containing the refrigerant substance it becomes cooled down to 0° Centigrade. This is ascertained by means of a thermometer introduced into the tube at some distance beyond the box, through an aperture which can be closed with a cork. Dr. de Tullio reports three cases in which severe hæmoptysis was arrested by this plan, when drugs, ice to the chest, and the other usual measures had failed. It does not, of course, cure the condition on which the bleeding depends, but it is an effectual remedy for the symptom.—*Medical Recorder.*

SCARLATINAL RHEUMATISM.—Ollivier, in a recent lecture delivered in the Hopital des Enfants Malades, treats of the swollen, painful joints which often complicate or follow scarlet fever. As to the nature of scarlatinal rheumatism, he thinks that this is a complication, and not an intercurrent affection; in other words, we have here a malady which has sprung up under the influence of scarlet fever, and which is only an exaggeration of certain phenomenon determined by this disease. Sennert came near the truth when he said that toward the close of scarlet fever the peccant matter attacks certain of the joints and inflames them. Although Blondeau, eighteen years ago, thought that he had established a parentage between scarlatina and rheumatism, both having among their manifestations arthritis, sore-throat, endocarditis, and cutaneous lesions, the erythema nodosum being to rheumatism what the scarlet eruption is to the other disease, there is really nothing but a certain analogy to support this view, while the two diseases are clearly separated by their origin, their symptoms, and their effects. The view is much the more probable that the arthritis of scarlet fever, like the endocarditis and pleurisy which sometimes accompany this specific fever, is but the manifestation of the exanthema on the serous system in general. The most of these arthrites, formerly called secondary rheumatisms, merit the name of infectious arthrites. They are, in fact, pseudo-rheumatisms, such as one meets in the course of divers diseases: blennorrhagia, puerperal fever, dysentery, erysipelas, even tuberculosis. By what processes are these morbid phenomena of the serous membranes brought about? It is probable that they are due to the irritation determined by certain micro-organisms which penetrate these closed sacs, being conveyed by the blood; in fact, recent bacteriological investigations have more than once proved the presence of microbes in the joint liquids of infectious arthritis. As for the prognosis of scarlatinal rheumatism, it is relatively favorable, this complication generally terminating in recovery. It will not do, however, to forget that the joints may suppurate, and that the patient is then especially in danger of vegetant endocarditis, or of suppurative pericarditis.—*The Boston Medical and Surgical Journal.*

THE TREATMENT OF DIARRHŒA IN PHTHISIS.—Dr. Polyák, of Görbersdorf, gives in the *Orvosi Hetilap* the results of some trials he has made of two recently suggested remedies in the diarrhœa of phthisis—viz., silicate of magnesia in the form of talc which has been recommended by Debove, and lactic acid recommended by Drs. Sézary and Aune. About eight ounces of talc were well shaken up in a pint of milk, and this or even a larger quantity was given daily. As a rule, it arrested the diarrhœa after having been used for a couple of days, but if it was left off the diarrhœa returned. It was found, however, that patients liked the milk mixed with talc even better than ordinary milk, but it could not be taken for more than six or seven days, as after that time complaint was made of a troublesome feeling of oppression in the stomach and bowels. Dr. Polyák thinks it quite impossible that long-continued use of talc can heal intestinal ulcers. Lactic acid proved in his hands a much more satisfactory remedy. The initial dose employed was thirty grains per diem in four ounces of water; this was increased subsequently, but not more than seventy-five grains per diem were given. On the third day the diarrhœa and the pain were generally arrested, and during the next day or two the stools assumed their ordinary character. It was found advisable to continue to give small doses for some time longer. The patients bore the treatment well; it produced no diminution of appetite, and, unless continued for a long time, gave rise to no disagreeable symptoms. Dr. Polyák thinks it possible that even ulcers of the intestines may be healed by this means.—*The Lancet*, May 18, 1889.

TREATMENT OF DIPHTHERIA.—At a recent meeting of the Société Médicale des Hôpitaux, M. Gaucher mentioned the fact that he had cured seventeen cases of serious diphtheritic angina by a new method—namely, ablation of the false membranes, and antiseptic cauterization of the mucous membrane. He added that M. Dubousquet-Laborderie (St. Ouen) had treated 81 cases by this method in four years; 4 of the patients succumbed to croup, but they were under the age of five; and the false membranes had already extended to the larynx when the treatment was applied. There were no toxic symptoms in any case, although the urine was black, showing that the treatment acted generally as well as locally. M. Gaucher employs a solution of 5 to 10 grammes of crystallized carbolic acid in 10 grammes of alcohol, adding 70 centigrammes of tartaric acid to render the solution antiseptic. After scraping the throat thoroughly with a short-haired brush he applies the solution. This operation is repeated three times daily. Every two hours the mouth is washed out with a 1 in 100 carbolic-acid solution.—*British Medical Journal.*

A POPULAR REMEDY FOR ASCITES.—In some places a popular belief is prevalent that dropsy may be cured by drinking the fluid removed, and patients often submit to a tapping for the sake of securing the fluid rather than because they have any faith in the curative effects of the operation itself. Dr. Duhamel, not long ago, published in

the *Gazette Médicale de Strasbourg* a case in which this method of treatment was put to a practical test, the result being such as to justify to the full the high opinion previously held of its efficacy. The patient was a man, aged fifty-seven, who was admitted into the hospital with an enlarged liver, due to excessive spirit drinking, and consequent ascites and œdema. He was tapped, and a large quantity of fluid withdrawn, but the peritoneal cavity rapidly refilled, and it was found necessary to repeat the operation at intervals varying from one to five weeks. This treatment was continued for about two years, during which period he was tapped fifty-three times. On the last occasion the patient asked whether he might drink the liquid that had been withdrawn, and though advised against it, he nevertheless secured some of the fluid, and drank about half a pint of it. He suffered no ill effects from his unpalatable potion, but on the contrary the dropsy did not recur, the œdema cleared up, and in four or five weeks the man was enabled to leave the hospital, a firm believer in the curative virtues of ascitic fluid. He reported himself some months later, during which time he had resumed his employment, and neither the dropsy nor the œdema had recurred, although the liver was still perceptibly enlarged.

Prophylaxis of Phosphorus Necrosis.—At a recent meeting of the Académie de Médecine M. Magitot read a paper on phosphorus necrosis. From sixty-five cases which he has observed in France and abroad, M. Magitot concludes that the affection is produced by the phosphorus introduced into a speciál form of caries, which he terms penetrating caries. The prophylactic measures consist in thoroughly ventilating and isolating phosphorus factories, and in suppressing or neutralizing the phosphorescent atmosphere. No persons of defective constitution should be allowed to enter the factories, more especially when the mouth is affected. If these measures be rigorously observed all danger of phosphorus necrosis will be averted.—*British Medical Journal.*

Heroic Treatment of Pneumonia.—The Russian peasants have little faith in expectant treatment, and believe that disease is an enemy that can be overcome only by powerful weapons. Nekrasoff, a Russian poet, in his "Red-nosed Frost," depicts graphically the treatment that is pursued in pneumonia, which is not very dissimilar in some respects to that followed by some of our brethren in Germany. When the patient came home sick, after being exposed in a snow-drift for several days, his mother poured cold water over him from a watering-pot, and then put him in a hot bath. But this brought no improvement, and then they called in the old women of the village, and on their advice gave the patient a good rubbing and then put him several times in a sweat-box. These measures failing, they gave him a cold bath by letting him down into a hole in the ice, and followed it up with a sweat in the hen-roost. The poet remarks that the poor man submitted to all this like a dove, but got no better notwithstanding. Then a peddlar, who happened to drop in, suggested that they put the patient under a bear so as to have him well kneaded. At this point, however, the wife interfered, and forbade further torturing of her husband, and the poor fellow soon after died in peace.

Eruption of Teeth in Old Age.—Mr. George E. Fisher reports in *The Lancet* the case of a lady, aged sixty-four, who asked him to lance her gums as they were very painful, having kept her awake for several nights. On examining the gums of the upper jaw he found a well-developed new canine tooth protruding, and the corresponding side full and painful, feeling to the touch distinctly as though a tooth were coming through. The patient had lost her incisor and canine teeth in the upper jaw some ten years before.

Long Sleep from Sulfonal.—The case is related in the *Deutsche Medizinal Zeitung*, No. 35, 1889, of a workman who took a tablespoonful of sulfonal in order to get "a good sleep." At the end of half an hour, as he felt no effects from the drug, he took two tablespoonfuls more. He then went out for some beer; but had taken only about half a glass when he became so sleepy that he left the balance and went home to bed. This was on January 5th, and he knew nothing more until the forenoon of the 8th, when he was awakened by being violently shaken. He recognized the people about him, but fell asleep again almost immediately. On the 9th he was again awakened by his wife, and remained awake from one o'clock until eight. He then fell asleep again, after having eaten a hearty meal with relish, and slept until seven o'clock the next morning, when he got up and went to work, feeling very well and much refreshed after his sound slumber.

England and the Opium Trade.—It was recently moved in Parliament that, at the next revision of the Tientsin treaty, the Chinese Government be allowed to extinguish the opium trade if it thought fit. The resolution was, however, opposed by Dr. Farquharson, on the strange ground that the opium habit was not as bad as the alcohol habit, either in its effects upon the system or in its relation to crime; and on the strength of this flimsy argument the resolution was defeated by a vote of one hundred and sixty-five to eighty-eight. There are said to be twenty-five million opium-smokers in China, and the number of deaths directly attributable to the effects of this poison reaches one hundred thousand annually. When some thousands are drowned by floods in the Hoang Ho Valley, the world is shocked, but the fact that ten times as many people are sacrificed every year in consequence of the forced importation of opium into China moves the English merchant not a whit.

A Popular Belief in the Contagiousness of Phthisis.—In a paper on the contagiousness of pulmonary phthisis, read at the twenty-fifth anniversary meeting of the Caucasian Medical Society, Dr. Babayeff mentioned the curious fact that among the Georgians the name for consumption is "chlekki," meaning "the contagious disease." When one of their number is found to be suffering from this disease he is at once isolated, and is taken to a hut or tent at some distance from the village. The care of these patients is entrusted to an old woman who carries to them the necessary food and drink, and they are never allowed to associate with the well.

An Honest Admission.—"It is with the most profound consternation that I have to report these five cases of death, due without any doubt to the treatment employed by me," is the way that an honest writer in one of our foreign exchanges begins his article. It is often more instructive to read of others' errors than of their successes, and it is a praiseworthy undertaking for one to report his mistakes; but not many would have the courage to do so in such a blunt fashion.

Vaccination on the Leg.—A French practitioner, in the course of a large number of revaccinations, was struck with the fact that the operation was far more successful whan performed on the leg then when the arm was selected. He has since availed himself of an opportunity of verifying his first impression, and last year, having to revaccinate 177 school children, he chose the left leg in 99 and the left arm in 78, and carefully compared the results obtained, dividing them into three groups according as the eruption was typical, doubtful, or absent. Of the 99 cases vaccinated on the leg, 23 were typical, 31 doubtful, and 45 unsuccessful, being equivalent to a percentage of 23.2 and 31.3, respectively. Of the 78 children vaccinated on the arm, the numbers were 11 typical, 25 doubtful, and 42 failures, equal to 14.1 and 32 per cent., respectively. The percentage of failures was 45.45 on the leg, as compared with 53.84 on the arm.—*Medical Press and Circular.*

### A NEW ANTISEPTIC DRESSING.

BEING AN ADDRESS DELIVERED BEFORE THE MEDICAL SOCIETY OF LONDON, NOVEMBER 4, 1889.

BY SIR JOSEPH LISTER, BART., F.R.S.,

PROFESSOR OF CLINICAL SURGERY IN KING'S COLLEGE, LONDON.

MR. PRESIDENT AND GENTLEMEN: When I last had the honor, five years ago, of addressing this Society, at the request of its President, I brought before you an attempt I had made to utilize the powerful antiseptic properties of corrosive sublimate without the great disadvantages attendant upon its highly irritating qualities. I had ascertained that when corrosive sublimate precipitates albumin, the precipitate is not, as had been generally supposed, an albuminate of mercury, that is to say, a combination of albumin as an acid with mercury as a base; in other words, that the albumin does not displace the chloride from its combination, but that the bichloride of mercury retains its properties intact, the albumin being loosely associated with it, in a species of solid solution, if I may so speak.

Further, I had found that this precipitate, even after drying, is capable of being dissolved in the serum of the blood, and that the solution in blood-serum is powerfully antiseptic, while not irritating. I proposed and brought before you a new dressing in the shape of what was termed the sero-sublimate gauze, charged with a solution of corrosive sublimate in the serum of the blood. This gauze gave very satisfactory results, both in my own hands and in those of surgeons in places so far distant as Poland and Spain. Nevertheless, it was not all that could be desired by any means; it was somewhat harsh mechanically; it was not very absorbent, a serious defect, and one of the materials of which it was made, the serum of horse's blood, was not always easily obtainable. I was, therefore, well disposed to look for something superior.

A few weeks after that communication was made to the Society, a firm of manufacturing chemists, Messrs. Gibbs, Cuxson & Co., wrote to me saying that they had found that if chloride of ammonium or sal-ammoniac in quantity equal to one-fifth part of the weight of the bichloride of mercury was added to the mixture of bichloride of mercury and blood-serum, the result was a much more fluid preparation than I had obtained. If I used a preparation of one part of bichloride of mercury to one hundred of blood serum, I got a thick liquid somewhat difficult to diffuse in gauze. They therefore suggested that by adding sal-ammoniac in that proportion I should get a much more workable arrangement. On consulting chemical works, I found that one-fifth of sal-ammoniac was exactly sufficient to produce, with bichloride of mercury, the salt long known to chemists as sal-alembroth, a double salt of bichloride of mercury and chloride of ammonium. I naturally wished to ascertain whether this addition of sal-ammoniac would impair or even destroy the antiseptic properties of the bichloride of mercury. I therefore made experiments on the point, and I found that the sal-ammoniac associated in the form of a double salt with the bichloride of mercury did not by any means impair its antiseptic properties; on the contrary, it improved them, so far, at least, as it concerned that which we have to deal with as surgeons, an albuminous fluid like the serum of the blood. Sal-alembroth and bichloride of mercury proved to be exactly equivalent, weight by weight as antiseptics in such a fluid. Each had to be used in normal serum of specific gravity of about 1.025 in the proportion of nearly $\frac{1}{1000}$, to prevent altogether the development of micro-organisms. Those who are acquainted with Koch's researches will consider this a very high proportion. Koch has shown that in a solution destitute of albumin, $\frac{1}{100000}$ part of bichloride of mercury is sufficient to prevent the development of organisms; but when we have albumin present in the solution, the case becomes altogether altered. Albumin interferes with the antiseptic action of corrosive sublimate, and thus in serum of the blood of specific gravity 1.025 we require, as I have already said, as large a proportion as about $\frac{1}{1000}$ instead of $\frac{1}{100000}$.

When the albumin is small in amount, less corrosive sublimate proves efficient. Thus in a case of spermatocele, where the specific gravity of the fluid was exceedingly low—only 1.007—I found that $\frac{1}{10000}$, just intermediate between the proportions required, blood-serum and water, was efficacious. On the other hand, when blood-corpuscles are mixed with the serum in the same amount as in the circulated blood, making the albuminoid substances much more abundant than in serum, we require proportionately more of the corrosive sublimate; at least 1 to 500 is required for the purpose of preventing development. This is a most important consideration after an operation. In the first twenty-four hours the discharge contains a large amount of blood-corpuscles as well as the serum, while, at the same time, it is the most copious, more copious than it will be in any subsequent day, provided all goes well aseptically. It is, therefore, an exceedingly serious consideration that in the first twenty-four hours we have a discharge which in both these respects tests our antiseptic more severely than it will ever be tested again, both from its abundance and from its quality. Still the sal-alembroth, whether used with blood-serum or with a normal mixture of serum and corpuscles, such as that obtained by whipping the blood of the ox so as to get rid of the fibrin, proved equivalent antiseptically to bichloride of mercury.

I may, perhaps, say in a few words how the experiments were conducted. For the purpose of ascertaining whether a given antiseptic can or cannot prevent development of organisms, a very simple mode of experimentation suffices. What we have to do is to ascertain whether it is *inhibitory;* not whether it is *germicidal.* The only special apparatus required for such experiments is a warm chamber, which can be kept pretty constantly about the temperature of the human blood. Beyond this a few stoppered bottles, with well fitting stoppers—perhaps half-ounce stoppered bottles—are really all that is required. Into a series of such bottles serum of the blood, to the amount, say, of one hundred and fifty grains, containing solutions of the antiseptic of different strengths is introduced. These are all inoculated by means of a small syringe pipette, with the same quantity, say $\frac{1}{16}$ of a minim of some potently septic liquid such as blood-serum in a state of advancing putrefaction. The bottles are placed in the incubator, and then, if development takes place, that is evidence that in the bottle in which it occurs such proportion of the antiseptic as that bottle contains is inadequate; if no development occurs we have proof of antiseptic efficacy. The transparency of the blood-serum

permits a recognition of the development of the organisms, which invariably causes opacity. If we have no change in this respect, if the serum maintains its transparency, at the same time keeping its odor unimpaired, and, further, if microscopic examination of any little sediment there may be shows that it contains no organisms, we have clear evidence that the antiseptic in the proportion concerned has proved efficacious.

Now, if the sal-alembroth was equivalent to the bichloride of mercury, weight for weight, that shows that the sal-alembroth was really more efficacious as regards the quantity of bichloride of mercury it contained. The bichloride of mercury having the sal-alembroth added to it, and also water in the double salt that is formed, is increased in atomic weight very considerably; and therefore if an equal weight of alembroth is equal in antiseptic action to bichloride of mercury, that shows that the bichloride of mercury is made more efficacious in the blood-serum by the addition of the chloride of ammonium. The chloride of ammonium in combination protects the bichloride of mercury, so to speak, to a certain extent, from the interfering influence of the albumin.

At the same time, the sal-alembroth proved much less irritating than bichloride of mercury. Experimenting on my own skin, I ascertained that it has certainly not half the irritating property of corrosive sublimate. The chloride of ammonium attached to the bichloride of mercury, while it protects the bichloride in some degree from the influence of albumin interfering with its antiseptic operation, prevents it also from acting so powerfully on the human skin. And thus the union of sal-ammoniac with corrosive sublimate had the double advantage of rendering it both more efficacious antiseptically and much less irritating.

Hence I was at first much pleased with sal-alembroth. But it soon appeared that there were certain disadvantages attending it. These depend very much upon its excessive solubility. It is essential for a satisfactory antiseptic dressing that the antiseptic should not be readily washed out of it by the discharge. Sal-alembroth is so exceedingly soluble that it is washed out with the greatest ease; thus we were always, even if we used large masses of sal-alembroth gauze, in fear that when the discharge was copious the antiseptic would disappear, say within the first twenty-four hours, and then the septic mischief would have an opportunity to enter. There was another disadvantage from this great solubility. When the discharge entered a mass of the sal-alembroth dressing it dissolved out the alembroth from it, passed into another part of the dressing, and there took up another portion of the sal-alembroth, and so went on from part to part of the dressing until, if the discharge was copious and the dressing large, as it must be when the discharge is copious, before the discharge got to the edge of such a dressing it became so concentrated a solution of the sal-alembroth as to be highly irritating. We have seen, for instance, after the removal of the mamma, when the first dressing is changed on the following day that there has been over the scapula and the neighborhood a huge blister. No doubt that was only a temporary inconvenience. We never had the discharge again so great as in the first twenty-four hours; but still it was a great inconvenience.

Such being the disadvantages of sal-alembroth dressing, I was disposed to seek for something better. I may say that I myself have never published anything in favor of sal-alembroth dressings; I have never been satisfied with them. It has leaked out that I have used them, and they have come into extensive employment, but never with my published sanction.

In the course of the following year I made various experiments in the hope of rendering sal-alembroth more useful in different ways, with which I need not trouble you, but without much success. In February, 1886, my attention was drawn by Mr. Martindale, of New Cavendish Street, to cyanide of mercury as possibly a valuable antiseptic, and, if so, having this advantage, that it did not coagulate albumin. I therefore proceeded to make experiments with cyanide of mercury, and I found indeed that in inhibitory power it was remarkably efficacious. I have said that with blood-serum sal-alembroth or bichloride of mercury is required in about $\frac{1}{100}$th part. I found that the cyanide of mercury kept blood-serum, with only $\frac{1}{1000}$th part, perfectly free from organic development, in spite of inoculation with potent septic fluid, for a month, when the experiment ended. I may remark that we have in cyanide of mercury a striking instance of the discordance that there may be between inhibitory power and germicidal power in an antiseptic. In inhibitory power the cyanide of mercury is, as we have seen, exceedingly high; but in germicidal power it turns out to be very low. Mr. Cheyne has made experiments for me, which have shown that even $\frac{1}{100}$th part in water is incapable of destroying the germs of bacteria. Still the inhibitory property of cyanide of mercury was a most important point if in other respects the salt were not disadvantageous; but, unfortunately, it proved to be so highly irritating that the greater irritating property of the cyanide of mercury more than counterbalanced its superior inhibitory power. It naturally occurred to me that the cyanide of mercury might perhaps combine cyanide with some other and form a double salt, having advantages corresponding with those presented by sal-alembroth as compared with bichloride of mercury. I tried the soluble double cyanide of mercury and potassium, but found it quite too irritating. I here again consulted Mr. Martindale, and he mentioned to me that in Watt's "Dictionary of Chemistry" it is stated that a double cyanide of mercury and zinc of very slight solubility may be formed by mixing together a solution of the double cyanide of mercury and potassium with a soluble salt of zinc, the zinc taking the place of the potassium. I therefore obtained some of this material, and proceeded to make experiments on it. I found, in the first place, that it was quite insoluble in water. This seemed at first extremely unpromising. It was soluble in about 150 parts of glycerine, but insoluble in water. I found, however, that it was soluble in about 3,000 parts of blood-serum, and therefore it was possible that it might work antiseptically. I made experiments to ascertain whether such was the case or not, and I found that this zinco-cyanide of mercury, as we may call it, had really most important antiseptic properties; that in the proportion of $\frac{1}{5000}$th part it kept blood-serum perfectly free from the development of organisms for eighteen days, in spite of potent septic inoculation.

I then tried experiments with serum and blood-corpuscles as presented in the whipped blood of the ox. On instituting comparative experiments between sal-alembroth, cyanide of mercury, and this double cyanide, I found that with the alembroth all proportions lower than $\frac{1}{400}$th putrefied within twenty-four hours after septic inoculation, while with the cyanide of mercury $\frac{1}{800}$th part sufficed to preserve the serum and corpuscles from putrefaction. At the same time, with the double cyanide I was much surprised and much pleased to find that $\frac{1}{1200}$th, half as little again, was sufficient to keep the mixture of serum and corpuscles permanently free from putrefaction. It may be said that the absence of putrefactive odor is but a rude test; there may be organisms developed without any putrefactive odor being present. That is perfectly true. At the same time, if in a given experiment we find that with one agent putrefaction occurs within twenty-four hours with $\frac{1}{400}$th part, while with another salt there is no putrefactive odor after the lapse of weeks with $\frac{1}{1200}$th part, we have pretty conclusive evidence that, so far as the mixture of corpuscles and serum is concerned, we have a more efficacious antiseptic in the latter. I therefore proceeded to prepare dressings of this new substance, diffusing it—for it is an exceedingly fine powder—in water with a little glycerine added to fix it, to prevent it from dusting out. If you simply diffuse it in water and pass gauze through it, with nothing more than the water, the result is

that you have gauze which, with the slightest touch, gives out the double cyanide in a cloud of dust, which produces not only inefficacy of your dressing by loss of the proper proportion of the substance, but becomes in the highest degree irritating to the nostrils of those who are near. A little glycerine, however, prevented the double cyanide from dusting out. I proceeded to try it in practice. I confess I did not dare to use it—considering its very slight solubility in serum—unmixed [redacted] I associated with it some of the very soluble cyanide of mercury; and with this cyanide gauze we tried various experiments in the way of dressing and got some admirable results. But then, on the other hand, there were disappointments. We found, for one thing, now and then very troublesome pustules as the result of a peculiar kind of irritation. Another disadvantage was that occasionally we got suppurations, coming on at a late period in the case, such as we had never been accustomed to with our carbolic dressings. A case might go on perfectly well for, say, ten days, and then suppuration might occur about a stitch track and spread perhaps farther; and sometimes the healing of cases was greatly protracted by this late suppuration. In consequence of these two circumstances, I gave up the use for the time being of this material.

I then directed my attention to biniodide of mercury, which has been highly spoken of for its antiseptic powers, and which has the advantage over alembroth of being comparatively little soluble either in water or in serum. I found that the iodide of mercury gauze answered our purpose very well so far as its antiseptic properties were concerned, but that it had the great disadvantage of producing irritation, which it was extremely difficult to control. In order to control it we interposed between the iodide of mercury gauze and the skin unprepared gauze, except in so far as it was steeped in a weak solution of bichloride of mercury (1 to 4,000). But we found that different skins differed greatly in liability to this irritation. The iodide of mercury, which is so very slightly soluble, as you know, in water, is much more soluble in serum, and the solution in blood-serum becomes irritating. In consequence of this, we had the same disadvantages from irritation as we had with the alembroth; and although, as in the case of the alembroth, this was only a transient inconvenience, I became dissatisfied with the iodide of mercury gauze. There was, however, one point of considerable interest, both theoretically and (as it turned out afterward) practically, which we found in this investigation with the iodide of mercury. If we simply charged with iodide of mercury, say from a solution in spirit of wine, and then applied the gauze so prepared, we found that the particles of iodide of mercury tended to gravitate down toward the skin, and there produce the most fearful irritation. It was absolutely necessary that it should be fixed. I tried various means, and among the rest a solution of starch, and then there came out this remarkable fact, that if a solution of starch is used with one of the ingredients employed for forming the biniodide of mercury by mixing a solution of iodide of potassium with solution of bichloride of mercury—if you dissolve the iodide of potassium in a weak solution of starch—the iodide of mercury thus formed in the nascent state associates itself with the starch particles in the most intimate manner and becomes entirely precipitated along with the iodide of mercury; so that if you take a drop of the red fluid formed by mixing these two solutions, and place it on a piece of calico, the watery material is absorbed by the calico and passes into the surrounding parts without coloring them, while the red spot with its insoluble iodide remains. If now you take a little iodine water, and apply it to the part of the calico moistened by the fluid that has exuded, you find that the iodine water produces no blue color of iodide of starch, showing that there is no starch in the fluid that thus oozes out and leaves the iodide of mercury behind; whereas, if you take a simple solution of starch and apply it as such to a piece of fabric, as far as the fabric becomes moistened so far do you get a blue color with the iodine. Here we have, as it seems to me, a somewhat analogous case to the so-called albuminate of mercury. We have the starch particles associated with the particles of iodide of mercury: the starch remains as such, the iodide of mercury remains as such; still they are attached to each other. And so the result was that when such a red solution produced by mixing these two liquids was used for charging gauze, the iodide of mercury was stuck to the gauze by means of the starch, and we had a most satisfactory arrangement in that respect. The iodide of mercury could not be washed out by water, nor did it in the least dust out. The value of this observation with reference to our present subject will appear shortly.

Being dissatisfied with the iodide of mercury, I turned my attention again to the double cyanide of mercury and zinc. Looking back to my notes, I found such evidence of its superior antiseptic properties that I felt that we had deserted this material too readily. In the interval we had had other experience of importance with the alembroth gauze. Occasional late suppurations had at first occurred under its use, just as was the case with the double cyanide gauze. These, however, had ceased to trouble us after my attention had been directed to the expediency of always using mercurial dressings in a moist condition. If they are used dry, the mercurial salt having no volatility, and having no power therefore of destroying any microorganism in contact with it, however obtained, whether derived from the manufactory or elsewhere, there could be no security that the dressing when applied was free from living organisms. This important object could, however, be infallibly attained if the dressing were used moist with an efficient germicidal solution. I put this idea into practice, and during the two years that have since elapsed, we have never on any single occasion had to complain of these late suppurations. Might not the same immunity attend our cyanide gauze if we adopted with it the same expedient?

The other objection to this double cyanide gauze had been the irritation which it occasioned. Might not this have been due to the simple cyanide, which, as I have said, I used along with the double cyanide? The simple cyanide is highly irritating, and, just as with the sal-alembroth, being freely soluble, it can be taken up by successive portions of discharge, and, when the discharge is free, may come to be in so strong a solution as to irritate. On the other hand, experiments on my own person had shown that the powder of the double cyanide might be kept applied to the skin for an indefinite time, whether moistened with water or with blood, without occasioning any irritation whatever. If this was really the explanation, and if the double cyanide could be trusted of itself, we might easily get rid of all irritation by using a double cyanide dressing moistened with a weak solution of bichloride, say 1 to 4,000, which, while it is securely germicidal, can never irritate. But here arose a new difficulty. I have told you that when we tried this double cyanide in a gauze at first, in order to prevent its dusting out, with its great inconveniences, we used glycerine: but if we moistened the gauze with 1 to 4,000 solution of corrosive sublimate, we should run great risk of washing out the glycerine, and then the double cyanide would be free to dust out on drying. And, besides that, it must be admitted that the glycerine arrangement was not a good one, independently of that consideration, inasmuch as when the discharges flowed into the gauze they would wash away the glycerine, and then the double cyanide might be washed out also, and so fail in one of the most important requisites of an efficient antiseptic dressing—the storage of the antiseptic in the dressing in spite of the discharge. How was this difficulty to be overcome?

Now came to our aid our experience with the iodide of mercury and the starch. Might it be that the particles of the double cyanide might attract starch as those of the iodide had done? It did not seem very likely, seeing that cyanogen is not known to have the special affinity

for starch that iodine has. Still, I thought I would try the experiment. I prepared the double cyanide by mixing a solution of the double cyanide of mercury and potassium with a solution of sulphate of zinc. I tried this with one of the ingredients, dissolved in a starchy solution; and, to my great satisfaction, I found that the precipitated double cyanide left a supernatant liquor almost absolutely free from starch, and that the particles which thus fell, the double cyanide with the starch associated, fixed themselves to a gauze in such a way that it did not in the least dust when dry. Not only so, but immediately after being charged with the precipitate diffused in water it might be washed in the wet state without the double cyanide being washed out of it, so closely did the starchy particles stick the double cyanide to the fabric. It is of great importance that in some way or other the double cyanide should be washed, because at the same time that an insoluble double cyanide is formed there are produced other double cyanides which are soluble and which are in the highest degree irritating; they must be washed out.

Well, I thought I had thus attained my object, and that by mixing starch with one of the two solutions necessary for forming this double cyanide and allowing the precipitate to form, pouring in more water, and, after precipitation, decanting and repeating the process another time, so as to get rid of all the irritating soluble salts, and then diffusing the precipitate through a gauze, I should have all that I desired. But when I tried to get this done by a manufacturer I found that I got blundering after blundering in such a way as to make the thing practically hopeless. There was nothing for it but in some way or other to get the double cyanide from the chemist as a definite article, and then in some way devise a means of fixing that powder of the double cyanide to the fabric. I therefore naturally tried whether a solution of starch would answer this purpose, whether the starchy particles would associate themselves with the double cyanide particles, not only in the nascent state, which we had before tried, but also when the already formed double cyanide was mixed with the starchy solution. I found that it did so; that when a starchy solution was stirred up with the double cyanide in the proportion of one part of starch to two of cyanide, the starch was almost all precipitated, and the precipitate so formed adhered to the gauze in the most satisfactory manner.

But though its adhesion was satisfactory enough, it turned out that the precipitate thus formed aggregated into a tenacious mass, which could not be diffused uniformly through the gauze, and here I was again at fault. This difficulty was overcome by first charging the gauze with the double cyanide powder diffused in water, and then transferring it to a starchy bath. This at once fixed the cyanide in the gauze; and whereas, before it was placed in the starchy bath the slightest squeeze made a milky fluid exude, no sooner had it been well penetrated by the starchy liquid than you might squeeze it as you pleased and nothing came out but a clear fluid. I was much pleased with this, and it is in this way that I have prepared the gauze that I have used for the last twelve months, both in the hospital and in private practice. Still, this method had its disadvantages. When the gauze had been passed through the fluid in which the double cyanide had been diffused without any starch, it required very tender handling. If you gave it a squeeze, out came a quantity of double cyanide; and it was plain that, although one might do it oneself satisfactorily, if we trusted to the manufacturers there would be an utter uncertainty as to what quantity of material might ultimately remain in the gauze.

Only lately has this difficulty been overcome. It occurred to me that perhaps if the starch were first blended with the double cyanide, and then dried and reduced to powder, if water were afterward added to this dried dissolved starch associated with the cyanide, there might not be the same tendency to lumpiness and difficulty of diffusion. I found that the process did not answer quite as I hoped in the first instance, in this respect, that the dried starch and double cyanide were extremely difficult to scrape off from any plate on which they were put to dry, and also very difficult to pound up and to diffuse for charging the gauze. But I got rid of these inconveniences by means of sulphate of potash, used for the same reason as in the preparation of Dover's powder—an inert substance, but with sharp, gritty particles. Mixing a pretty strong solution of starch with the double cyanide powder, and adding to this a quantity of pounded sulphate of potash, the result is that you get a material which, after drying, is easily scraped off by the manufacturer and easily reduced by him to an impalpable powder, which is then readily diffused in water, and makes a perfectly uniform gauze; being mixed in large quantity with water in order to charge the gauze, the sulphate of potash is practically got rid of, and if any of it remains it does not harm, because it is inert. Thus we have the means of easily charging the fabrics with this double cyanide.

I have spoken of diffusing this preparation in water, but in reality we employ for this purpose the 1 to 4,000 solution of bichloride of mercury, which fortunately does not in any way interfere with the process. I may remark that the double cyanide, like the simple cyanide of mercury, though very efficient as an inhibitor, cannot be trusted as a germicide. There are different ways in which absorbent gauze such as this may be charged. One is to pass it folded in about sixteen layers through a trough, such as the one before me, which I have myself used, having a bar near the bottom to insure the gauze being kept well under the liquid. It is then, as soon as you please, squeezed to press out superfluous liquid, and then, if wanted for immediate use, a simple way is to place the masses of gauze—say, six-yard pieces—in a folded sheet, turn the folded sheet over them, and roll it up. The folded sheet then absorbs the still redundant liquid, and you have moist gauze ready for use in five minutes. For the use of the ordinary surgeon it will probably be best to have the gauze dried, on the understanding that it is again moistened with 1 to 4,000 sublimate solution before being used. Here is a sample of the gauze in the dry state, which you see does not give off dust when freely handled.

Other articles may be charged as well as gauze with this substance. The double cyanide being perfectly unirritating in its own substance, it is no objection to having an excess of it. If you take, therefore, some of the preparation and stir it up with water, so as to produce opaque liquid, and put linen rags into it, and then place them in a folded towel to take out the excess of liquid. you have your dressing ready prepared for you then and there. It can thus be very easily worked on an emergency.

We have seen that the double cyanide requires about three thousand parts of blood-serum to dissolve it. If, therefore, it is present in a gauze in the proportion of about three per cent., you will easily understand that blood-serum may soak through such a gauze time after time without washing the ingredient all out; so that it is a material which is admirably stored up in the dressing. That is one of its three great advantages, the others being that while trustworthy as an antiseptic it is completely unirritating. In actual practice the few layers placed next to the wound are washed in a solution of carbolic acid; this washes out the corrosive sublimate which, though present in small amount, might irritate the wound to some extent. The carbolic acid soon flies off, and there is left in the application next the wound merely the unirritating double cyanide, and under this we find that not only do wounds, the edges of which are brought accurately together, unite beautifully by first intention, but even granulating sores heal by the gradual process of cicatrization from the edges—heal by scabbing in a way that we have never seen under any other dressing.

Having satisfied myself that this was really a useful material, I proceeded to request a manufacturing chemist

to provide it for me on a large scale. Messrs. Morson & Son, of Southampton Row, kindly undertook to do this, and I have to thank them for the great pains they have taken in carrying out experiments on this subject at my suggestion. Their manager, Mr. Taubman, soon informed me that in his opinion there was exceedingly little mercury in this so-called double cyanide of mercury and zinc. Very little mercury could be got from it on testing in comparison with what would be obtained if it were a true double salt. He asked if I was sure that the cyanide of zinc was not after all the thing that was efficacious? Was the idea of the double cyanide altogether a delusion? I need not say how much pleased I should have been if such had been the case—if we could have had the cyanide of zinc without any poisonous mercury in it as an antiseptic. The cyanide of zinc was a perfectly definite compound, there could be no mistake about it. I proceeded to make experiments, and I found, indeed, that cyanide of zinc has antiseptic properties. I made, for instance, experiments of this kind—I took a piece of glass tube like that which I hold in my hand, and packed it with gauze charged with cyanide of zinc only, and then, holding it vertically, poured serum of horse's blood into it till the gauze was fully moistened; and then poured more in, till a quantity dropped out from the lower end equal to that which had produced saturation, the gauze being thus thoroughly washed with the serum.

I then inoculated the top of the gauze with a potent septic drop. I had another such tube with gauze that had no cyanide of zinc in it, and I inoculated that in the same way. I then put each into a well-fitting stoppered bottle, so as to prevent any evaporation, and placed them in the incubator. At the end of four days I opened the two bottles. That which contained the gauze without the cyanide of zinc stank, and, on taking portions of the gauze from either one end or the other, squeezing them, and examining under the microscope the fluid that escaped, there were seen teeming multitudes of bacteria of various sorts. The bottle with the cyanide of zinc, on the other hand, had a pure odor of hydrocyanic acid, which this gauze always has. I then examined drops squeezed from both ends, and I found no bacteria in the clear serum that was pressed out, not only from the lower end, but even from the upper end, in the immediate vicinity of the inoculating drop, and where the gauze had been drenched repeatedly with the serum.

Now that, so far, is a result such as no other antiseptic had ever given me. Take iodide of mercury, for example. Comparatively insoluble as it is, if you pour blood serum upon it in such profusion you wash the iodide of mercury out, and if you inoculate septically the part so washed you induce bacteric development. The test applied was, of course, an extremely severe one. In actual surgical practice the discharge which pours into the dressing is pure to begin with, supposing the wound to be aseptic at the outset. The septic agency only acts upon the dressing from without, and in a far milder form than here, where a potent septic drop was used. Thus we had clear evidence that the cyanide of zinc really is an antiseptic. On the other hand, it turned out to be not so powerful antiseptically as our double cyanide so-called. In order to compare the two salts I made another experiment similar to that last described. I packed three pieces of glass tube with gauze in two inches of their length, one of the gauzes being charged with cyanide of zinc, another with the so-called double cyanide (neither of these gauzes having been treated with solution of bichloride of mercury), while the third gauze was unprepared. Serum of horse's blood was poured into the upper end of each vertically-held tube till it thoroughly soaked the mass of gauze, after which each gauze was inoculated septically at the centre of its upper end. The tubes were then placed vertically in stoppered bottles in the incubator. It happened that in the septic liquid used for the inoculation that I used there was, among other organisms, a species of streptococcus which had a remarkable power of producing an acid fermentation in blood-serum. After four days I proceeded to examine the contents of the three tubes. In the unprepared gauze there was utter putrefaction; in the gauze prepared with cyanide of zinc only no putrefaction had taken place, but acid fermentation had occurred. Both at the upper and lower end of the gauze litmus paper was reddened on application to the serum. In the putrid gauze turmeric paper was most intensely reddened, much more so than by normal blood-serum, an alkaline fermentation having occurred there. On the other hand, with the gauze that contained the double cyanide, with mercury as well as zinc, both at the upper and at the lower end the turmeric paper was reddened exactly as it was by the normal blood-serum. This state of things continued the next day; but on the following day, six days after the commencement of the experiment, I found that at the upper end, in the vicinity of the inoculated spot, this gauze purpled litmus, while at the lower end it still reddened turmeric. At the end of seven days the same condition persisted. After eight days, however, both the upper and lower end of the gauze purpled litmus. This peculiar septic organism, with the power of producing acid fermentation in serum, had gradually worked its way, in spite even of the cyanide of zinc and mercury; but the cyanide of zinc and mercury, you observe, had been much more efficacious than the cyanide of zinc alone. The cyanide of zinc had prevented the development of organisms that produced putrefaction, and only permitted the growth of the coccus that produced acid fermentation. Cyanide of zinc and mercury had for several days prevented all development. This was proof, therefore, that the mercurial element in our compound was valuable, and that we could not dispense with it.

It may be thought an unsatisfactory thing that there should have been any organism able to work its way thus through a gauze charged with our antiseptic. But I may remark, in the first place, that we tested the material exceedingly severely with our potent inoculation; in the second place, that it was a long while before the organism penetrated the gauze even for a short distance; and, in the third place, that penetration of micro-organisms through such a dressing into wounds does not seem to occur in practice, seeing that in the year during which I have used this antiseptic in my surgical work at King's College Hospital we have had no single instance in which we have had any reason to suspect septic change in the deeper parts of our dressing; we have had no instance in which deep-seated suppuration has occurred in an operation wound made through unbroken integument. If we have had any pus at all in such cases, it has been from the surfaces exposed between stitches or at situations where drainage-tubes have been inserted, and what I have termed antiseptic suppuration has shown itself, and even this in very slight degree. Such being the case, I feel not only permitted but bound to bring this material under the notice of my professional brethren.

As to the composition of this so-called double salt, it is for the present uncertain. This much is already established: that the cyanide of mercury is in very much smaller proportion to the cyanide of zinc than Watts' "Chemistry" would lead us to expect the double salt would give. But what the precise composition of the salt is we do not yet know. I am having it investigated by the Pharmaceutical Society, who have kindly undertaken the work.

There is another use for this material besides the charging of dressings. The powder, moistened with a weak solution of corrosive sublimate, may be rubbed into hairy parts, when it will convert the hairs into an antiseptic dressing. Not long ago a medical friend of mine brought his wife to me with no less than seven sebaceous cysts in the scalp, requesting me to remove them. Having washed the hair with a 1 to 20 carbolic-acid solution, I simply passed a comb over each tumor in the line where I was about to transfix, without shaving at all; and, after taking out the cysts, rubbed some of the moistened powder

into the hair in the vicinity. I then applied a dressing of cyanide gauze, and I was glad to learn that all the seven wounds had healed without disturbance.

We have now in the hospital a case of psoas abscess, shown to be of spinal origin, not only by the history of the case and the symptoms, but by the discharge of a portion of both with the pus. That case is pursuing a course which, allow me to say, psoas abscesses will pursue in the great majority of cases, if the surgeon uses a trustworthy antiseptic, and takes the same pains with dressing to the last as at the outset; that is, he will find his trouble rewarded by the complete cure of these formerly incurable cases. I say this because I grieve to think that these psoas and lumbar abscesses still seem to be regarded as hopeless affairs by many surgeons. In this man's case the temperature has never been affected in the least; he has put on flesh rapidly; the discharge, after the purulent and curdy matter that existed originally in the abscess was got rid of, has been of serous character, and is in small and diminishing quantity. But the opening made for the discharge is in the vicinity of the pubes, and the pubic hairs used, under such circumstances, to be a constant source of anxiety to us unless frequently shaved away. Here we rub in at each dressing a little of the moistened cyanide, and convert the hairs into an antiseptic application.

I will not at present enter into the details of the preparation of this material; these will be supplied in a note on a future occasion.[1]

The sketch which I have given you of this investigation, though it has, I fear, wearied you, conveys but a small idea of the toil it has involved. There are those who still believe that the use of antiseptic substances in surgical practice is always useless, if not injurious. The germ-theory of septic diseases is indeed now happily established incontrovertibly. All now admit that septic mischief in our wounds depends upon the development of micro-organisms in them derived from without. But the gentlemen to whom I refer are, more or less logically, disposed to trust everything to the antiseptic powers of human tissues.

I believe I happened to be the first to direct attention to the antiseptic agency of living structures, and there is perhaps no one who attaches greater importance to it than I do. Without it surgery in former days would have been absolutely impossible. Still I know too well from experience that it cannot always be trusted, and that the use of antiseptic adjutants is in the highest degree important. And I have the satisfaction of knowing that there is among you a constantly increasing number who, when they have operated on an unbroken skin, with a fair field around for the application of their dressings, if they see septic inflammation occurring in the wound with its attendant dangers, know that it is their fault or the fault of the antiseptic appliances at their disposal. To those among you who are impressed with this conviction I offer the dressing which I have described as the most satisfactory that I have hitherto met with; and I venture to hope that you will regard it as a not unacceptable addition to your resources.

---

"The Medical Mirror" is the name of a new journal which is announced to appear in January next. It will be issued monthly under the editorship of Dr. I. N. Love, and its place of publication will be St. Louis, Mo. Dr. Love's reputation as a medical journalist is sufficient to insure a hearty welcome to his new venture.

The Status of Cocaine in Surgery.—In the report of Dr. Wyeth's paper with this title read before the Virginia Medical Society, the strength of the solution, as given in the report, was one drachm to the ounce, and was said to approximate a four per cent. solution. The formula should have been: Cocaine muriate, gr. xx.; boric acid, gr. iij.; distilled water, 1 ounce.

[1] This note will appear in our next issue.

## FRACTURES OF THE BASE OF THE SKULL.

By FREDERIC S. DENNIS, M.D.,

NEW YORK.

Mr. Chairman and Gentlemen: In thinking over a topic upon which to address the Surgical Section of the Academy this evening, it occurred to me that a subject embracing certain injuries of the head might not be inappropriate. I shall, therefore, invite your attention to this surgical lesion, because it is one of very great importance, and also because the special consideration of it has not hitherto engaged the attention of the Section. There seems to have been of late a tendency, or a fashion, among surgeons to consider the new operations *only*, and a trite subject like fracture of the base of the skull has not received its share in the surgical discussions of the day. The time has come when surgeons should direct their attention toward modifying and improving some of the olden methods of treatment, and not be carried away entirely with the technique of some modern operations.

Fracture of the base of the skull has been one of those injuries which the surgeon has treated purely upon the expectant plan, and with the conviction that death is sure to follow. This view of the lesion has been entertained for years by hospital surgeons, and there is certainly a consensus of opinion among surgical writers in regard to the prognosis in this injury. All the standard text-books and monographs are in accord in reference to the mortality. During the past few years my attention has been especially directed to a study of these cases of basilar fracture, and I shall endeavor to demonstrate this evening that fractures of the base of the skull are amenable to surgical treatment. I shall also endeavor to point out the clinical fact that the great majority of these cases die from causes which can be wholly prevented by the surgeon. There has been but little encouragement to the medical man to attempt any treatment in these cases of basilar fracture, when one reads, as he may, in the latest edition of a large standard work on surgery, "that any treatment directed to the lesion itself is out of the question." I trust that I can demonstrate this evening the incorrectness of this view, which represents the opinions of most surgical authors.

Fractures of the base of the skull may be situated in any of the three fossæ of the cranium. They may be divided into three varieties:

1. Where the fracture involves the anterior fossa, the roof of the orbit, or the nasal cavity.

2. Where the fracture involves the middle and posterior fossæ.

3. Where the fracture involves the posterior fossa.

The first variety is seen in falls upon the forehead, or by an umbrella or cane thrust through the roof of the orbit.

The second and third varieties, where forces act from below, as a fall from a height where the patient strikes upon the tuberosities of the ischium or upon the vertex of the skull.

The *signs and symptoms* of fracture of the base of the skull slightly vary according to the seat of the injury. There are, however, three signs and symptoms that are nearly always present. These are, 1st, hemorrhage; 2d, escape of cerebro-spinal fluid; 3d, coma. There is no value to be attached to any one of the three; but when they are found together, the diagnosis is certain. In regard to hemorrhage, the source of it is most important to consider. If the anterior fossa is the seat of fracture, the bleeding occurs from the nose or from the mouth, and usually there is subconjunctival ecchymosis; if the middle and posterior fossæ are involved, the hemorrhage is from the ear and occasionally from the nose. It must be noted that, in cases of non-rupture of the membrana tym

[1] Read before the Surgical Section of the New York Academy of Medicine, November 11, 1889.

pani, the blood may escape into the nose and pharynx and enter the stomach. Hemorrhage in such a case may exist, but there are no external evidences of it. The first intimation that the surgeon has of the existence of hemorrhage is hæmatemesis. Absence, then, of hemorrhage from the ear or nose is not conclusive evidence of the non-existence of a basilar fracture. On the other hand, the presence of bleeding alone from the ear is not in itself a diagnostic sign of any value as indicative of fracture of the base. At one time I collected sixteen cases of hemorrhage from the ear, in no one of which did a fracture of the base of the skull exist, and in all of the cases recovery took place. The late Dr. Loring was kind enough to go with me, and he made some interesting observations upon this point at the time. The blood, in some of these cases, came from a lacerated membrana tympani, and in other cases from a wound of the soft tissues in the canal. When the hemorrhage occurs in basilar fracture the source of it must be from the petrous portion of the temporal bone, from the internal carotid, or from the lateral sinus. If from the last two named sources, the cases terminate fatally. Extravasation of blood near the mastoid process, or in the suboccipital region, is significant when there is no external bruise to account for the ecchymosis. The difference between a black eye and subocular extravasation must be made. In the orbital extravasation due to fracture in the anterior fossa the blood is behind the conjunctiva, and is greatest in amount in the posterior part of the orbit. This variety of ecchymosis usually appears suddenly, and if it does it is strongly in favor of fracture of the base. The black-eye ecchymosis is chiefly in the lid or in the connective areolar tissue just beneath the orbital ridge. The ecchymosis is not present immediately after the injury, but comes on any time from a few hours to a few days.

The *second* sign is the escape of cerebro-spinal fluid. This is a valuable diagnostic sign. The fluid escapes by a transverse fissure in the petrous portion of the temporal bone, and through a tear in the arachnoid membrane that surrounds the auditory nerve. The fluid may even escape from the nose in fracture of the anterior fossa. This I have seen also in cases of fracture in the middle and posterior fossæ where the membrana tympani was not ruptured and the fluid was directed through the Eustachian tube. In another case the cerebro-spinal fluid emerged from the mouth; but this is exceedingly rare. The cerebro-spinal fluid comes from the ears in considerable quantity, and the discharge continues for many days. If the fluid is examined, it is found to be nearly all water with a specific gravity of about 1.002, and holding in solution a large quantity of chloride of sodium, little or no albumin, but a trace of sugar. Saliva has been mistaken for the cerebro-spinal fluid. This has happened in cases where the condyle of the lower jaw has fractured the meatus, and under these circumstances saliva may escape into the canal. The small amount of the fluid and its composition enables the surgeon to distinguish it. It was formerly supposed that the liquor Cotunnii from the internal ear supplied this watery discharge, and by some the discharge was thought to be filtered serum. Both of these views have been proved to be incorrect. The cerebro-spinal fluid has been seen associated with the escape of slight shreds and minute particles of brain-substance. This complication makes the diagnosis absolute.

Deafness is a condition dependent upon the escape of the cerebro-spinal fluid, and is probably caused either by pressure on the nerve from hemorrhage, or else by laceration of the nerve, although at the time the patient is not usually in a state of mind for this symptom to be of any value.

*Coma* is present in a greater or less degree, according to the severity and situation of the fracture. There is nothing peculiar in this symptom in basilar fracture, except perhaps that the coma is associated with more jactitation and restlessness than in coma the result of cerebral hemorrhage. The paralysis is connected with the cranial nerves rather than those which are affected in hemiplegia. The local cranial nerve affections are usually obscured by the coma. A study of the functions and movements of each cranial nerve in fracture of the base is very difficult during the existence of coma; but a careful study of the physiological action of each cranial nerve will reveal approximately the extent to which the lesion affects the origin of that nerve. It is thus, by collective evidence, that knowledge can be acquired as to the extent to which the brain has been injured in connection with fractures of the base of the skull.

With a view to simplifying the general subject of basilar fractures, I shall advance two propositions, and shall attempt to prove the correctness of these propositions.

1. That fractures of the base of the skull should be considered in the same category as compound fractures of the vertex of the skull or of the long bones.

2. That since fractures of the base of the skull possess the same essential characteristics as other compound fractures, they should therefore be treated by the same exact principles of aseptic surgery.

In regard to the first proposition, that a fracture of the base of the skull should be considered in the same category as compound fractures of the vertex of the skull, and the long bones. Some surgeons may dissent. It is evident, however, that every compound fracture has air admitted to the seat of the fracture, and this is the case in reference to fractures of the base of the skull. If the anterior fossa is the seat of lesion, air gains entrance through the nasal cavities. If the middle and posterior fossæ are involved, then air gains access to the seat of fracture either by the external auditory meatus, or by the Eustachian tube through the pharynx and nasal cavity.

The entrance of air to the seat of fracture, which is a *sine qua non* for the existence of a compound fracture, is not the only point that basilar fractures possess in common with all other compound fractures. The basilar fracture is associated with hemorrhage, with laceration of nerves, with venous thrombosis, with septic phlebitis, with fat-embolism, with cerebro-spinal shock, with pyæmia—in fact, with all the complications that arise in other compound fractures. The visceral lesion is not confined to basilar fractures, because it occurs in fractures of the vertex. It is thus evident that fractures of the base do not differ in any essential particular. The view may be even advanced that the local lesions in vertex fractures may be more severe than basilar fractures, because in the latter variety the cerebro-spinal fluid in a measure protects the brain from direct violence and lessens the shock.

I trust that I have made conclusive the points involved in the first proposition. And now, as to the second proposition advanced, viz., that since fractures of the base of the skull possess the same essential characteristics as other compound fractures, these fractures should be treated according to the same exact principles of aseptic surgery.

A discussion of this second proposition naturally brings us at once to a consideration of the treatment of compound fractures in general.

It is wholly unnecessary in this paper to refer to the management of compound fractures. All surgeons are agreed upon the following principles: Antiseptic cleansing of the wound, immediate immobilization, proper drainage, and permanent fixation. It remains to be shown that these same principles can be applied in fractures of the base. The technique is simple. Every patient suffering from fracture of the base, if the immediate shock is not too profound, should be removed to the operating-room if a hospital patient, or to a room especially prepared if in private practice. I have always insisted upon this point, because the hospital ward is not the place to dress a compound fracture. The risks of suppuration are too great to expose such a wound to the air of an ordinary surgical ward. Every outside preparation having been made to make the toilet aseptic, the head should be held firmly and the entire scalp shaved, after which it should be thoroughly washed with soap and water, and then irri-

gated with a 1 to 500 bichloride of mercury solution. Attention should next be directed to the irrigation of the external auditory canal and the nasal cavities. Both of these should be rendered thoroughly aseptic, after which the ears should be packed with iodoform or bichloride gauze and some absorbent cotton plugs placed in the nose. The air can filter through cotton, but micro-organisms cannot pass through it. In irrigating the nasal fossæ the surgeon must exercise great care, lest the fluid enter the stomach and produce toxic effects. There remains now only one other possible channel of infection to the seat of fracture, and that is the Eustachian tube. This may carry sepsis to the interior of the cranial cavity in a fracture of the base. The arrangement of the ciliæ in the tube is such as to propel air and mucus toward the nasal cavity; but during the act of deglutition the current may be reversed and infection thus reach the base of the brain. In the ordinary form of fracture of the base, where the membrana tympani is ruptured, the discharges make their exit through the auditory canal. In the exceptional cases where the membrane is not ruptured, the blood, serum, and cerebro-spinal fluid find their way into the nasal cavity and the pharynx, and thus these cases are most exposed to sepsis. If the unruptured membrana tympani is examined in a basilar fracture, the membrane will be puffed out on account of the presence of fluid behind it, and the membrane will have lost its natural lustre. These are the circumstances under which it may be wise to puncture the membrana tympani, and thus allow the blood and the cerebro-spinal fluid to escape through the external auditory canal. The diversion of the discharge from the Eustachian tube into the ear makes it possible to keep the fluids permanently aseptic. Having now rendered the head and all the avenues of approach to the intracranial cavity aseptic, it remains to apply a dressing that will keep these parts permanently free from any source of infection. This object is best accomplished by the use of a cap made of wet loose bichloride gauze or carbolized wool, over which absorbent cotton should be placed and a bandage applied. The cap should completely surround the entire head, cover in the ears, and protect every channel leading down to, and communicating with, the seat of fracture, and the cerebral viscera from the entrance of septic germs. This same dressing should be made from time to time during the repair of the fracture, and under the same strict and rigid rules of antiseptic surgery. The head should be held firmly by some dressing described in monographs upon bandaging under the name of the martingale dressing. This insures fixation to the head, and keeps the fracture as quiet as possible during the repair.

The reasons for dressing fractures of the base of the skull with a scrupulous attention to the minutest detail in antiseptic surgery are at once obvious. If a patient survives the immediate shock of the fracture and lives twenty four hours, he is almost certain to die shortly after from causes which can be directly attributed to sepsis. Among these causes may be mentioned basilar meningitis, cerebral abscess, pyæmia, suppuration in petrous portion of temporal bone, septic phlebitis, encephalitis, lepto-meningitis, and other complications due to infection.

If the surrounding parts and the discharges can be kept aseptic, then sepsis cannot occur, and this removes at once all the causes of death due to this agent. I do not pretend to state that it is impossible for a patient with fracture of the base to die except from a cause due to sepsis; but I do state that nearly all these cases terminate fatally from causes which are due to sepsis. A reference to statistics will demonstrate that deaths occurring in fractures of the base of the skull independent of sepsis are extremely rare, and that nearly all these cases die from causes that can be prevented by the surgeon. There is nothing original in this plan of treatment except that it is a report of my cases in which an application of antiseptic surgery has been made to a new class of fractures.

I would even go further, and recommend that all cases of head-injury associated with hemorrhage from the ear or from the nose be treated with antiseptic precautions. I have seen many cases where there was no reason to believe that a fracture of the base of the skull existed—and, in fact, it did not exist—but where a hemorrhage occurred from the ear or nose, and in the course of ten days a meningitis developed and the patient died. Every practical surgeon can recall cases such as I have mentioned, and I believe that the meningitis in these cases had its origin in the septic contamination of the hemorrhagic or other discharges.

The old and good rule in surgery, "never to look lightly on any injury of the head, however trifling it may appear," is one that, if observed to the letter, may be a means of saving a life where otherwise that life might be sacrificed.

With a view to making a practical demonstration of the principles involved in the management of these cases of fracture of the base of the skull, I have requested a patient who received a fracture of this kind, and who has since recovered, to come here this evening.

During the past few years I have had in my hospital experience a large number of fractures of the base of the skull. Most of these cases died from shock within twenty-four hours, but there are six patients who have recovered from this injury under the plan of treatment that has been suggested. I will briefly read the history of the case here this evening, and then present the patient to the Section for examination.

Albert James D——, aged twenty-five, admitted to the Harlem Hospital, December 8, 1888. Patient fell from top of a freight-car, striking his skull upon the rail. The ambulance surgeon found him insensible. There was hemorrhage from the nose, both ears, and from the mouth, and post-conjunctival ecchymosis of left eye. Left temporal region severely contused. Pupils dilated, breathing stertorous; pulse, 75 and strong; temperature, 98° F. Associated with the head-lesion was sprain of left knee-joint. Patient was very restless and at times very noisy. The following day was tied in bed and was wildly delirious. From both ears there was a discharge of a white fluid which upon examination was proved to be cerebro-spinal fluid. A few days after the accident he suffered from a severe glossitis which, with œdema, threatened his life. The glossitis was the result of injury to the posterior end of third frontal convolution and contiguous part of ascending frontal. For the following fourteen days from the receipt of the fracture of the base, there was a discharge of cerebro-spinal fluid from both ears. Magendie's solution, bromide of potash, and other sedatives were used. The patient was kept for some time in a straight jacket on account of the traumatic delirium. It is an interesting clinical fact that the patient now is oblivious to the accident, and he has no recollection of the time he spent in the hospital until he began to recover. This is certainly a test-case for any plan of treatment, for there was cerebro-spinal fluid escaping for two weeks, during which time the surrounding parts and the discharges were kept aseptic.

---

THE STAINING OF GONOCOCCI.—Dr. J. Schütz, of Frankfort, gives a method of coloring gonococci that may prove useful. The method is founded on the known resistance to acetic acid possessed by the gonococcus after staining with methyl blue. After the cover-glass is covered and spread with a thin film of the suspected substance, it is passed three times through a flame. It is then allowed to remain from five to ten minutes in a saturated solution of methyl blue in five per cent. carbolic water. It is then to be washed in water. It is then for one moment, or as long as 1, 2, 3 can be counted, to be dipped in acetic-acid water (acid. acet. dil., ♏ v.; aq., 20 c.c.), and immediately washed off in water. As the acetic acid solution decolorizes all other organisms more rapidly than the gonococcus, all except these will have lost their color while they remain distinctly blue.—*The Medical Press.*

## A CASE OF SARCOMA OF THE DURA MATER—LIGATURE OF THE LONGITUDINAL SINUS.[1]

BY FREDERIC KAMMERER, M.D.,

NEW YORK.

THE patient whose history I desire to relate this evening was a man sixty-eight years of age. Three weeks before his admission to the German Hospital he noticed a small tumor on the occiput. This had been incised a few days previous, but further interference was wisely deferred, when it was noticed that the swelling showed faint pulsations. The swelling was situated exactly in the median line, apparently at the upper angle of the occipital bone, was of the size of a walnut, and projected only slightly over the level of the skull. Its size was not diminished by pressure. The patient presented no symptoms of a general or local character referable to the brain. There was no history of syphilis. As the microscopical examination showed the growth to be a round-cell sarcoma, and as the lack of cerebral symptoms made it probable that the growth had developed to no great extent within the cranial cavity, the diagnosis of a periosteal sarcoma was made, and an attempt to remove the same was deemed justifiable. I accordingly circumcised the tumor, about half an inch from its border, down to the bone and chiselled off a corresponding part of the skull, laying bare the dura and the attachment of the growth to it immediately over the longitudinal sinus. The opening in the skull, which was larger internally than externally, the firm adherence of the growth to the dura mater, coupled with the knowledge that sarcomata developing from the dura on the convex surface of the brain have rather a tendency to immediate perforation of the skull, now made it evident that we had here to deal with a sarcoma starting from the dura itself. The greater part of the growth was readily removed, but its base, about the size of a silver quarter, was firmly implanted on the longitudinal sinus. As the removal of the entire mass would have necessitated the excision of the superior wall of the sinus, and as the extreme thickness of the skull suggested even at this time the possibility of a mistaken diagnosis, I decided to interrupt the operation and to put the patient on large doses of iodide of potassium. This was continued for several weeks, with the result that new tumor-masses rapidly filled up the opening in the bone. During this time I had, on several occasions, attempted to dissect the dura of the longitudinal sinus into two layers in the cadaver without opening the sinus itself, but had very imperfectly succeeded. At all events, I had received no encouragement to attempt this in the living. Three weeks later I operated a second time. As a preliminary step, the further removal of a ring of bone, to again expose such parts of the dura as were sound, became necessary. I then incised the dura on the left side and elevated it toward the middle line. This was easily accomplished at the superior margin of the growth, but at its inferior border, near the torcular Herophili, very free venous hemorrhage occurred on attempting to prolong the incisions through the dura. I now tried to approach the falx cerebri from the right side, as I had done from the left, my intention being to ligate the sinus and to raise the tumor, cutting through the falx toward the confluence of the sinuses. Unfortunately, the longitudinal sinus did not lie in what I had calculated to be the median line, but more to the right. Several attempts to get beyond it were unsuccessful, even after removal of some more bone. The patient was now in such a state of collapse that I was compelled to abandon the operation immediately. I returned the flap of dura on the left side, and, after tamponing the opening in the skull, I quickly loosened and withdrew the hæmostatic forceps from the sinus, making light compression with the dressings. Although there was immediate oozing through the latter, no further hemorrhage ensued. Three weeks later I ligated the longitudinal sinus, having enlarged the opening in the skull to the right. The flap of dura previously raised on the left had become intimately attached to the cortex cerebri, and in raising it a second time the upper layers of the cortex came away with it. The sinus was ligated with two strong silk ligatures and was cut between them, and an attempt was made to extirpate the tumor, as before suggested. This proving impossible on account of implication of the confluence of the sinuses, the greater part was removed with a sharp spoon and the wound tamponed as before.

On the second day after the operation, when the patient began to rally from his collapse, he complained of an impairment of vision. Only with great difficulty could he count fingers at a distance of several feet, and he could scarcely see the clock on the wall opposite his bed, on which he had always been able to tell the time. The powers of vision were much more defective in the right than in the left eye. As was anticipated, ophthalmoscopic examination revealed nothing abnormal. At about the end of a week his sight began to improve steadily and almost regained its former power. About a week after the last operation the patient began to complain of continual headache. Antipyrin gave some relief, as did also galvanization, but on the whole the pains became more severe, in spite of all attempts at their alleviation, until the patient's death, which occurred seven weeks after the ligature of the sinus. Two days before his death he became restless. On the day preceding it he was unable to speak, and his attention could not be attracted. No motor or sensory disturbances were recorded. He continually attempted to roll himself out of bed on the right side. He died the following morning.

The post-mortem examination showed marked nervous congestion of the convex surface of the cerebrum; no meningitis; the tumor, that had been almost entirely removed at the last operation, had again developed to a considerable extent, encompassing the median region above the torcular and projecting to either side as a spherical mass, a little more voluminous to the left, where it measured about one and one-half inch in diameter. The tumor had to a certain extent compressed the cortex cerebri in the region of the first occipital gyrus, and also invaded the cortical substance in this area. It had not reached beyond the parieto-occipital fissure anteriorly, and the sulcus interparietalis laterally, and had left the angular gyrus entirely intact. In the substance of the left occipital lobe, but more especially on the anterior aspect of the tumor in that location, an extensive recent hemorrhage was discovered. The longitudinal sinus was filled with adherent blood-clots, which extended into the afferent veins.

It appeared to me of some interest to attempt to explain the visual defection by the pathological conditions found. We know, from the experimental researches of Ferrier and others, that the centre of vision is lodged in the occipito-angular region, that the greater portion of both occipital lobes can be removed in animals without causing any appreciable impairment of vision, but that destruction of the angular gyri will lead to complete blindness, non-persisting, however, when the experiments have been conducted on an antiseptic basis.[1] Ferrier comes to the conclusion that blindness following destruction of the occipital lobes only depends upon "direct implication or secondary extension of the lesion into the angular gyrus." I believe that, following the last operation in my patient, during which the cortical layer of the left upper occipital gyrus was almost entirely destroyed and the brain subjected to many unavoidable mechanical insults, also on the right side, inflammatory reaction spread into the angular gyri and was the cause of the visual impairment. As this condition subsided, his sight became almost fully restored. Some time after the last operation, the brain being fully

[1] Read before the Surgical Section of the New York Academy of Medicine, November 11, 1889.

[1] Ferrier: Functions of the Brain, 1886, page 271 et seq.

exposed in the region of the upper occipital and, as I thought, perhaps also of the angular gyrus, I applied both the faradic and galvanic currents to the brain-substance with, I regret to say, negative results, even though the currents finally employed were very uncomfortably felt at the tip of the tongue.

Ligature of the longitudinal sinus has, to my knowledge, been only once attempted heretofore.[1] The case was one of traumatic injury, where, after the removal of loose pieces of bone, severe hemorrhage set in from a rent in the dura at about the highest point of the skull. The operator compressed the opening in the sinus and closed it, as he expresses himself, with sutures sufficiently deep to include the entire sinus. No untoward symptoms followed, and the patient made a perfect recovery. That wounds of a cerebral sinus can heal, and generally do so, without interruption of the continuity of the lumen, has been amply demonstrated by clinical experience as well as by experimental work.[2] It would appear that the majority of all lesions of the sinuses heal in this manner. In our times of antiseptic surgery, when we have learned to avoid the most dreaded sequence of traumatic thrombosis of a sinus, viz., infection, and on that account are less fearful in surgical manipulations of wounding it, such wounds generally heal without giving rise to any unfavorable symptoms later on. Whether this is also the case when a sinus, especially the longitudinal sinus, becomes completely obliterated, seems to me a question still *sub judice*. Bergmann[3] says, in this regard: "Partial or complete obliteration of the larger sinuses does not necessarily lead to persisting disturbance in the functions of the intracranial organs; indeed, they can exist a long time without any such." Not a very definite statement. We know that cases of idiopathic thrombosis, if I may thus express myself, of the large sinuses, especially the longitudinal sinus, generally terminate fatally. Motor excitation symptoms, mental depression, sleepiness, apathy deepening to coma, occasionally delirium, are the symptoms of marantic thrombosis. Very frequently cephalalgia, assuming an unusually severe character, is present. I suppose that in my case the severe pains in the head were directly attributable to the venous stasis after the ligature. The veins from the cerebral surface open into the longitudinal sinus in the main part posteriorly; before entering it, they receive the small branches from the mesial surface of the hemispheres. These, an occasional anastomosis of the superficial veins over the gyri of the convexity of the brain,[4] and an emissary vein through the parietal bone, seem to be the only collateral branches available, when the longitudinal sinus is occluded near the torcular. As a result of these anatomical conditions, sudden closure of the sinus by ligature ought to give rise to the symptoms of thrombosis and their pathological substrata (venous stasis, meningeal hemorrhage, and capillary hemorrhages of the cortex) even more rapidly than thrombosis which is non-traumatic. Certain authors[5] have taken the view that when mental depression and apathy are the only symptoms, the obliteration is only a partial one. Neither in my own, nor in the case previously cited, if that be one of complete ligature, did any immediate symptoms develop. May not the extreme anæmia in my own case account for this? As the patient gradually recovered and began to sit up in bed, thus making muscular efforts, pains in the head set in and increased in severity from day to day.

I regard the operative procedure in my case in the light of an important factor in the causation of the intracranial hemorrhage, of which the patient died. Exactly where the hemorrhage occurred I am not prepared to state. It must have been from one of the larger vessels of the cortex or the subjacent white matter, considering its location in the occipital lobe, or perhaps even from one of the meningeal veins, and directly dependent on the venous stasis. As a matter of fact, extensive hemorrhage does frequently occur in thrombosis of the longitudinal sinus.

In conclusion, therefore, I would say that ligature of the longitudinal sinus, as recommended by Heinecke[1] and Navratil,[2] is not an indifferent surgical procedure, and one the admissibility of which is still to be determined by further clinical observation, and chiefly by experimental research.

## FIVE REASONS FOR FAILURE IN TREATING CHRONIC RHINITIS.[3]

By THOMAS F. RUMBOLD, M.D.,
ST. LOUIS, MO.

THERE are numerous reasons why some physicians fail to successfully treat chronic rhinitis, but I will mention only five, any one of which would alone account for complete failure.

Since the last annual meeting of the American Rhinological Association, at Cincinnati, I have visited quite a number of offices of physicians who daily treat rhinal diseases. Of these offices I am permitted to speak plainly concerning the armamentaria of five. Each of these physicians has seen a copy of my criticisms, and is perfectly willing that my remarks shall be published *pro bono publico*. These physicians have a liberal education, literary and medical. All of them have the degree of A.M., and all of them have visited European hospitals. I say this to show that I am certainly taking a good average of intelligence of the profession, and men who have had better opportunities to study these diseased conditions than the great majority of physicians who attempt their treatment.

If, in speaking plainly of these physicians and their instruments and apparatuses, I seem too severe on others, I hope that it will be taken in good part, for I give it in the most kindly spirit, and because I have the advancement of my profession at heart.

The first reason for failure that I will mention is that of defective instrumentation.

There are three prominent faults connected with the instruments and apparatuses of these physicians that necessarily must cause their failure.

First. Not one of these physicians had a tongue depressor that would not cause the patient to retch as soon as it was introduced into the mouth. The blades of all these instruments were too wide to go between the teeth, and they were much too long also, being about six inches in length. These instruments were seldom used in examinations; the exceedingly defective method of drawing the tongue out with a napkin was employed instead. When these physicians used the right kind of a tongue depressor on themselves, while they were patients of mine, they were surprised at the marked contrast of the effects of the two instruments, for I had been careful to request them to try the effect of their own six-inch blade tongue depressor before using the one I had with me. A serious fault in the manner of using this instrument was that they applied it themselves on their patients' tongues, instead of allowing the patient to use it, thus almost compelling the patient's throat to spasmodically close, and in this way prevent any application to the pharyngo-nasal cavity and the posterior portion of the nares.

Four of these physicians declared, voluntarily, that my success was largely due to the use of the right kind of a tongue depressor, and because I allowed the patient to hold down his own tongue.

Second. The spray-producers that these physicians used were made for watery solutions only; they did not

[2] Navratil: Loc. cit.
[3] Read before the American Rhinological Association, October 9, 1889, at its Seventh Annual Meeting, held in Chicago, Ill.

possess an instrument that could throw warm vaseline. Liquid cosmoline was found in every office. While this remedy is far superior to tannin, iodine, nitrate of silver, or any of a dozen other agents commonly found in offices, yet it is very much inferior to warm vaseline. The fact that the cosmoline is in a fluid state is one of its attractive properties. In this shape the physician is spared the trouble of heating it, a sin of which the profession is frequently guilty, namely, avoiding any inconvenience, even to the neglect of the proper treatment of the patient. Although it is far more convenient to employ a cold liquid, yet it too quickly leaves the mucous membrane; besides this, heat is a very valuable adjuvant in the treatment of these chronic inflammations.

I doubt very much if one could cure a rhinitis of a man, thirty-five years of age, even with liquid cold vaseline, while cosmoline in any form is more or less irritating. Liquid vaseline will not remain long enough upon the mucous membrane, certainly not longer than one or, at most, two hours, as I have found after careful observation, while common vaseline may be found in the nasal secretions, by the aid of the microscope, forty-eight to eighty hours after it has left the instrument. Of course, treating rhinitis with aqueous solutions must end in failure.

Third. The compressed air used was taken from a container of a capacity of from three to four or five gallons. Air enough was forced into this reservoir to show a pressure of from thirty to seventy pounds. The reservoir was filled by an air-pump whose barrel was made of brass; the piston was packed with leather, which is partially decomposed animal tissue, and it was lubricated with rancid oil of some kind.

I asked these physicians if they had taken into consideration the comparatively large quantity of brass, as well as innumerable bacteria, emanating from the partially decomposed leather and positively decomposed lubricant that the compressed air had absorbed—certainly a hundred-fold more than would be absorbed by uncompressed air, and which was instantly deposited on the mucous membrane of the air-passages upon the removal of the high air-pressure. If anyone will try the experiment of passing air of this kind into a bottle of beef-tea, then pass air compressed by means of water-pressure into a similar bottle, he will see, by the aid of the microscope, the astonishing difference of the two airs. If he was to have one of these airs forced into his own air-passages, he would quickly decide to have the air that was not contaminated with the brass, leather, and rancid oil. One needs but allow some of this contaminated air to escape before his face, when his olfactories will soon detect the odorous qualities of the stream.

It is needless to say, to those who are acquainted with the subject, that the lowest air-pressure used by these physicians is fully three times greater than that which should be employed—ten pounds being the greatest pressure that the mucous membrane can stand without producing irritation, while by far the greater majority of patients require from only six to eight pounds' pressure. The object to be accomplished by the compressed air is to blow the secretion off the mucous membrane, and also to forcibly apply the medicament upon the cleanest surface. This it should do without causing the least irritation. All irritation, however slight, tends to retard recovery, if it does not increase the inflammation. Inspissated secretion requires a force of about ten pounds to completely coat it over. This force will remove but a small portion of the hardened secretion; to remove all of it would require a much greater force, but that force will cause irritation, which must not be instituted. With the reduction of the inflammation, aided by the softening of the secretion by the vaseline, the surface will soon be freed of the inspissated accumulation. Thick, purulent secretion will require from eight to ten pounds to blow it from its lodging-place; flowing muco-purulent secretion may be removed with a pressure of from six to eight pounds, and watery secretion, as is found in pruritic rhinitis, from four and a half to five and a half pounds.

The question may be asked: Were these five physicians less amply supplied with the proper kinds of instruments and apparatuses than most physicians who assay to treat these diseased conditions? Not at all. Their armamentaria are about as good as could be found in well-supplied offices in this country, Great Britain, or any other part of Europe. They are wealthy, ambitious, honorable men, and they had such instruments and apparatuses as their instructors in New York and Europe had themselves employed.

In closing my criticisms upon these physicians' methods, I ask: How is it possible to treat the posterior portion of the nasal passages when the tongue depressor that is employed is of such a shape and used in such a manner as to almost certainly cause the patient's throat to contract to its severest degree, thus shutting off all opportunity to reach the posterior nasal openings, for the upper and posterior portion of these passages cannot be properly treated through their anterior openings? Even if they could reach the diseased surfaces, they had nothing with which to treat but instruments that threw watery solutions or powders, or vapors. Again, if these very serious defects did not exist, the excessively high air-pressure would be injurious to the highly inflamed nasal passages. The patient might not complain at the time of the application, as many of them expect, or do not object to pain while under treatment; but it should be borne in mind that the anæsthetic condition of the membrane aids in covering any distress for the time being, but the next day the patient will complain of some new symptoms, which should be charged to the treatment received the day before.

There are comparatively few offices that have a sufficient number of instruments and apparatuses for the treatment of the diseases of the upper air-passages. No one would think that a man who intended to make a good living in selling dry goods, hardware, or anything else, was extravagant if he filled his store with from $5,000 to $50,000 worth of stock; but I have seen offices of physicians that would not bring $500—books, instruments, and furniture—even if sold at first cost, yet these men propose to earn a livelihood from this small outlay. Economy, with many well-to-do physicians, takes a prominent place when an instrument is to be purchased. Of course, efficacy is not entirely forgotten, but it does not, as it should do, hold a paramount place in their minds. A physician should not take into consideration his own convenience or his pocket when instruments, or apparatuses, or methods are to be selected; every consideration is due to his patient. The question that should be asked is, "Is this instrument or apparatus or method the best for the patient?" The cost or inconvenience cuts no figure what ever.

The next reason for failure is an anatomical one. I mean, by this, an error in locating the disease. Innumerable clinical observations, and almost innumerable post-mortem examinations prove conclusively that rhinal inflammation invariably commences on the superior and middle turbinated processes and extends in all directions in the nasal passages and into the passages connected with them, except on the floor of the nasal passages or so-called inferior nasal meatuses. It should be always borne in mind that these two portions are seldom affected with inflammation. There is another important fact well known to anatomists; that is, that the under surfaces of the four diseased turbinated processes cannot be thoroughly cleansed or treated through the anterior nasal openings, approach by way of the posterior nasal openings being absolutely necessary.

The only instruments I saw that could treat these surfaces were the posterior nares syringe and black rubber spray-producers, both throwing aqueous solutions. The syringe had generally been discarded because of the patient's vigorous protests against its use, and the black

rubber instrument was having the same kind of reflection cast upon it, the low temperature of the solution used, no doubt, being one of the causes of the unpleasant effects. A few still employed the nasal douche because of its former reputation, and because they do not know its injurious effects or were seriously impressed with the injury it does, besides being ignorant of the fact that it does not remove the secretion, and not knowing anything else that has the reputation of cleansing the coated cavities.

Another method of cleansing, as well as of medication, is the slender probe. This instrument is armed with a roll of cotton, plain or medicated; it is then thrust into the anterior nares, the first time being made to pass along the floor of the nasal passages, or the so-called inferior nasal meatuses—where there is little or no diseased mucous membrane—it is then made to pass into the middle nasal meatuses, and then into the superior nasal spaces, that is, if the patient could tolerate its passage six times. After these applications every patient's eyes were suffused with tears; the great majority blew a small quantity of blood from their noses. Another probe, bent nearly at right angles, was made to pass up behind the soft palate, and, when there, was made to wipe out this cavity.

The employment of these probes proved either that they were ignorant of the location of the disease, or were too easily satisfied with the futile attempts to reach the diseased surfaces. If these physicians had one thousand patients, and treated them all in this way, they necessarily must fail one thousand times to even ameliorate the complaint, and the great majority of chances are that they would injure everyone of the one thousand patients. Yet this is the method that many physicians have made extensive trips to Europe to learn. I have seen this method employed in Berlin and Vienna. This is not slander. In England but two or three men, up to 1884, recognized chronic nasal inflammation, and one distinguished writer says, in all earnestness, that this complaint is peculiarly American. Of course, he is mistaken. Rhinal disease is far more frequently seen in London than in any city I have ever visited. The fact is that the disease is recognized by but few English physicians.

In every case where there was a dry hacking cough, and, especially if the voice was affected, the probang was thrust down into the larynx, or toward it. As the disease was not in the location where the probang was passed, the patient would not be even relieved. If the patient persisted in visiting the physician but did not improve, the case was pronounced one of tubercular laryngitis, and he was recommended to live in a more salubrious climate. This is also transatlantic treatment.

Several patients who had a gagging cough in the morning were treated for stomach trouble. Nothing whatever was done for their nasal disease that occasioned the secretion that lodged behind the soft palate that in turn caused the gagging cough.

Fourth. The physiological reason.

The physiology of the nasal passages should be as constantly borne in mind as that of any other important organ of the body. Respiration, in health, is carried on almpst exclusively through the nasal passages. When constant mouth-breathing is necessary, the victim is constantly in distress, not only physically, but mentally. Now this is about the only function that the very large majority of operators seem to regard. As soon as partial or complete nasal stenosis is discovered, an operation for its relief is instantly urged, but, while restoring the function of nose-breathing, they utterly disregard every other function possessed by this organ. They attack the hyperplasia as though that alone was the disease; in fact, nothing else is done or recommended. The cause of the growth is not mentioned. Under these circumstances the patient, while relieved of the "stuffiness" of his nasal passages, is not in the least relieved of his rhinitis; on the contrary, the operation may have been so severe as to greatly aggravate the rhinal inflammation, as I have seen it in a number of persons who have come under my care after such operations. The fact that the function of the mucous membrane had become greatly impaired long before the formation of the growth that closed the passage existed, did not seem to enter the mind of the operator.

It is well known that scar-tissue does not perform all the functions of mucous membrane. While the air may be heated, or even overheated, yet the proper amount of moisture that is requisite for the pharynx, larynx, trachea, bronchial tubes, and air-cells is not present, consequently irritation of all of these lower organs commences from that time, and continues while the normal condition of the nasal passages exists. Not only this, but the nasal passages themselves will, because of their dry condition, give new evidences of new inflammation, which will greatly increase the whole trouble. This new inflammation will give rise to a superabundant flow of muco-purulent secretion. To check this we find the majority of physicians employing other means and other methods that again prove their ignorance of the functions of the nasal mucous membrane. For this trouble a few will employ inhalers, but by far the greater number use insufflators. I have seen, during the last year, at least a dozen varieties of instruments for throwing powders into the nasal cavities. All of them were nearly equally injurious, but those that threw the powder under the turbinated processes were by far the most injurious.

It is well known, but apparently forgotten, that the functions of the inflamed nasal membrane are but partially performed; it is also well known, and also apparently forgotten, that the normal condition of the mucous membrane is the moistened condition, yet these powder-blowing physicians attempt to restore the functions of this diseased mumbrane by drying its surface with a powder. A more preposterous act could hardly be conceived.

We are now ready to take up the fourth, the pathological reason.

How can these physicians escape the verdict of ignorance of the pathology of chronic nasal inflammation when they employ inhalations of vapors and insufflations of powders to cure this condition? Does the vapor or powder cleanse the thickly coated surfaces—surfaces that must be cleansed to be cured?* Do they think that these applications fall upon the diseased surfaces? Do they not know that these agents take effect only upon the surfaces that require the least treatment? Do they not know that the surfaces that most require treatment are not treated at all? It appears to me as though they must either plead ignorance of the pathology of this region or acknowledge malpractice.

Fifth. The etiological reason.

Inflammation of the surfaces under consideration is due to an enlargement of the blood-vessels, also to a very great increase in their number. This increase is more apparent than real, for these vessels existed long prior to the apparent increase, but they did not carry red blood-corpuscles, consequently they were not visible even under the microscope. This is readily demonstrated in the mesentery of the mouse, the foot of the frog, and the rabbit's ear. To permit the red blood-corpuscles to flow through vessels of a smaller calibre, the sympathetic nerves that control the muscles that surround these and all other blood-vessels are debilitated; they are in a paretic condition. This condition is due to injury done to sensory nerves by colds principally, but by other agents also, such as tobacco, alcohol, carbolic acid, etc. Unless the irritation was caused by these agents the sensory nerves would not act reflexly upon the sympathetic nerves, causing them to take on the paretic condition spoken of, and if this condition did not take place, there would be no such phenomena as inflammation, proliferation, hyperplasia, atrophy, œdema, ulceration, etc. In other words, without irritation inflammation and its sequences would not, nay, could not, exist. Keeping in mind that every irritation produces inflammation, what are the indications for treatment of chronic rhinitis?

1. The diseased secretion, which is always acrid, there-

fore irritating, should be removed. If morbid growths are present, as these also are irritating, they should be removed, thus removing the local sources of inflammation.

2. The new secretion, that is, that which is to be formed upon the surfaces that have been cleansed, should be prevented from becoming acrid, thus preventing another cause of inflammation.

3. Hygienic and sanative measures should be insisted upon. This is to prevent a continuance of the irritation to the sensory nerves, that are located upon the surface of the body and the mucous membrane, by colds and other irritating agents, thus removing the originating causes of the inflammation.

This is all that is required of the physician, or, far more correctly stated, that is all that he can do. *Vis medicatrix naturæ* performs the cure, if it is possible. The recovery will be rapid in the young, and slower as old age is reached.

Now, let us see if the methods and remedies mentioned will fulfil these three essential indications. They must fulfil all three, or a failure is sure to follow.

As already stated, the douche and the posterior nares syringe have very properly been abandoned by experienced physicians, because they do not remove the diseased secretions. The same must be said of the probe passed into the anterior nares, and up behind the soft palate, for the cotton cannot cleanse even the surfaces that they do reach, without, at the same time, producing excessive irritation, while the secretion under the four turbinated processes is not touched, and the secretion that is removed from the pharyngo-nasal cavity is not formed there, but originally comes from the upper portion of the posterior surfaces of the nasal passages, a region not attempted to be reached by the cotton applicator, and if attempted, would surely fail, as a portion of the parts affected and coated with purulent secretion cannot be seen except by a post-mortem section of the head.

It is evident that to fulfil the first indication—removing irritating secretion without causing additional irritation—is a complete failure. Yet this is about all that is done by men in this country and Europe who have a world-wide reputation for being scientific practitioners.

I claim that it would be truly wonderful if they cured a single case of chronic rhinitis. In fact, nature would be compelled to change her laws in order that she could perform a cure for them.

The second indication is not thought of; certainly not mentioned by any of the books, domestic or foreign. Maybe someone would say that the insufflation of a powder proved their attempt to prevent the secretions from becoming more decomposed, but the degree of irritation due to the powder that covered the surfaces that had no catarrhal accumulation, surfaces that did not require treatment, is greater than the benefit that could accrue from preventing the unremoved secretion from becoming further decomposed. Besides this, the irritation of the clean surfaces, due to the action of the powder, will cause the whole of the mucous membrane to pour out a superabundance of mucus, so as to wash out all the catarrhal accumulation on which the powder was lodged, thus putting a stop to the necessity of the corrective action of the powder.

I am much pleased to notice that the books published in this country during the last few years are calling attention to the third indication, namely, hygienic and sanative measures. Still, these measures are so slightly enforced by the physicians that the patients are not impressed with their importance. A great many physicians are victims of some of the habits that are conducive to catarrhal inflammation, consequently consistency prevents them from enforcing rules against tobacco-smoking, chewing, snuffing, the use of beverages that contain alcohol, keeping late hours, short hair-cutting, etc.

What relationship is there between the effect of iodine applied to the pharyngo-nasal cavity and the etiology of the inflammation in this cavity? a diseased condition that is due to a flow of secretion from still more diseased surfaces located two inches above it. Is this a scientific application? No one will claim that the iodine allays irritation. Its curative property depends, I believe, on its being an antiseptic, that is, correcting the acridity of the secretions to be removed. Even if this secretion should be allowed to remain and be corrected, does this allay the inflammation in the upper portion of the posterior nares, the location that originated this secretion? Supposing that the secretion is removed by the same instrument that applies the iodine, then there is nothing for the iodine to correct. The very same may be said of nitrate of silver, iodoform, preparations of mercury, etc. All of these agents injuriously affect the sensory nerves of the inflamed mucous membrane, these nerves act reflexly upon the sympathetic nerves that go to the blood-vessels of the same membrane, and in this way give rise to additional inflammation, the very opposite of what is intended.

It is seen that the mucous membrane of a patient treated in this way has three sources of irritation: First, the original one, from the sensory nerves of the integument, caused by colds; second, from the acridity of the secretion formed upon its surface; and, third, from the iodine or nitrate of silver or the insufflated powder.

What use is there in cumbering a book with the etiology of a disease if it does not guide one in the use of medicines or methods for its alleviation? If one reads the pathology and etiology of the nose and throat in foreign and domestic works, they will see no more relationship between these important subjects and the practice recommended than there is between a railroad time-table and a sheet of opera-music. It is a pure waste of time to read them, if one expects to be assisted in comprehending the course laid down for treatment. I have not seen a physician that read them more than once, and not one of these was reminded as to the means or methods of the treatment while reading them.

To conclude: When medical men fail to use instruments that will reach the location of the disease, when their efforts at treating the disease demonstrates that they do not know its location, when they are seemingly regardless of the function of the mucous membrane, when they treat a coated catarrhal surface with a vapor or a powder, and when their local applications and operations show that they have no etiology to guide their practice, nothing less than failure should be expected. Under these circumstances it should not be expected that a case of common chronic rhinitis would be ameliorated, not to say cured. It is innumerable fruitless efforts of this kind that has filled the world with expressions of positive doubt as to the curability of this disease. It is quite common for intelligent persons to say: "I fear that nasal catarrh cannot be cured. I have not seen a person that was cured, nor have I ever heard of one that was cured."

---

Seeking a Resting Place for the Dead.—Efforts have been made on various occasions to provide mortuaries in Paris for persons who, for any reason, were not domiciled anywhere at the time of their death. A painful instance of the inconvenience resulting from the want of them occurred recently. A journalist, in the last stage of phthisis, feeling better one day, took advantage of this to induce his brother to bring him in a cab from the outlying suburb, where he had been residing, into Paris. He, however, succumbed soon after passing the *barrière*, and then began, for the brother, a tedious and horrible promenade. Refused at his own hotel, declined at the hospital, on the ground that it was not a mortuary, rejected at the Morgue because only the unidentified dead were received there, the whole night was passed in perambulating in the cab the dead body of his brother that nobody would receive. It was only by a derogation from the rules of one of the hospitals that the brother was enabled to find a temporary resting place for the deceased.—Paris Correspondent *Medical Press and Circular*.

## SOME OF THE RECENT APPLICATIONS OF MENTHOL.

IT is only within a few years past that menthol has been used to any extent in medicine, and even now its employment is rather restricted—more so, perhaps, than its merits deserve. What these merits are, and in what conditions menthol has been found to possess some curative properties, it may be profitable briefly to consider.

The most familiar employment of this camphor is as a local application for the relief of pain, and menthol cones are prepared and sold in the shops for this purpose. The relief obtained by such applications is usually but temporary, yet in some of the milder forms of facial neuralgia and so-called rheumatic pains the remedy is of real service. In pruritus also the analgesic properties of the drug have been turned to good account. It is employed for this purpose in ointment, spirit, or liniment, in the strength of from one part in twenty to one part in ten. A very good preparation for this purpose is that recommended by Eloy, of a solution of fifteen grains of menthol in one ounce of forty per cent. alcohol. Still another use for the remedy, as externally applied, is in the treatment of furunculosis, and more especially of furunculosis of the external auditory canal. Here the bactericidal properties of the drug, as well as its analgesic action, come into play. Dr. Cholewa has made trial of menthol in these cases and commends it most highly. He applies it by means of a pledget of cotton moistened with a twenty per cent. solution and inserted into the canal. The application is said to cause a little smarting at first, but this is soon succeeded by entire relief of pain and a speedy subsidence of the inflammatory process.

Ringworm of the scalp is said by Dr. Malcolm Morris to yield more promptly to applications of menthol than to any of the ordinary remedies employed for this purpose. One part of menthol, four of chloroform, and twelve of olive-oil is the formula recommended in such cases.

In the treatment of various affections of the upper air-passages, also, good results have been obtained by local applications of menthol in the form of solution, vapor, or spray. Rosenberg and others have claimed quite a large percentage of cures of laryngeal phthisis by this means. In this country Potter, Knight, and others report very decided improvement after the use of menthol in this disease, but they have not observed any actual recoveries. In nasal and pharyngeal catarrh much benefit is often derived from sprays of menthol dissolved in oil or fluid vaseline in the strength of from one to twenty or thirty per cent. In hay fever William Hill, of London, has found menthol to serve an excellent purpose as a substitute for cocaine. He applies a ten or twenty per cent. solution in olive- or almond-oil to the sensitive area within the nose by means of a brush or atomizer.

In the chronic bronchitis of old age Nyes speaks favorably of inhalations of menthol, which, he says, not only facilitate and rapidly diminish the expectoration, but also allay the cough and reduce the number of paroxysms. These inhalations have also been used with good effect in whooping-cough. Finally, the same mode of application has proved useful in Jores' hands in relieving asthma. He reports a case for which all the usual and most of the unusual remedies had been tried unsuccessfully. Inhalations of a twenty per cent. solution in olive-oil were then tried, with the most satisfactory results—the rattling râles disappeared almost immediately and the respiration soon became normal.

Menthol has not yet been employed to any great extent internally, although it is said to act efficiently when so given in controlling certain painful affections. Dr. C. L. Dana has so employed it, with fairly satisfactory results, in migraine, supra-orbital neuralgia, and anæmic headaches. The dose for internal administration is from fifteen to sixty grains per day. These are some of the uses to which this drug has been applied, though they are by no means all. If the effects obtained should be found to be uniformly produced, we might well be justified in placing menthol among the most valuable of the minor therapeutic agents.

---

## INTRATRACHEAL INJECTIONS OF OIL OF CREOSOTE.

DR. LOUIS DOR, of Lyons, has contributed to the *Revue de Médecine* an article upon the above subject. Over a year ago Beehag stated that he had successfully injected mentholated oil into the trachea of persons suffering from phthisis. The injections were made directly through the tracheal wall by means of a hypodermic syringe. This method, however, was too barbarous ever to be widely adopted, even if good results could be obtained. Dr. Dor therefore decided to make injections directly through the larynx, by means of a syringe specially constructed for the purpose. He also chose creosote in preference to menthol because of its stronger anti-microbic power. According to Bouchard about one-tenth per cent. solutions of creosote (0.80 per 1,000) kill the bacillus in pure cultures, while, according to Guttmann, one gramme to the litre retards its development. The solution used by Dor consisted of 5 grammes of creosote to 100 c.c. of sterilized olive-oil, and of this from eight to thirty drops were injected. The injections caused, in some persons, temporary choking and distress, and sometimes vomiting, but never hæmoptysis. The patients generally soon became accustomed to the medication and ceased to be disturbed by it. Experiments made upon rabbits showed that the oil gradually reached the alveoli of the lungs, and was not entirely absorbed for several days. Dr. Dor does not report any brilliant cures, but, like most of the new methods of treating phthisis, it gives relief to the cough and causes improvement in other symptoms. Further and extended details are promised at a later day.

### PARENCHYMATOUS INJECTIONS OF IODOFORM-OIL IN JOINT DISEASES.

A FEW years ago a good deal was written concerning the use of iodoform in the treatment of abscesses in tuberculous joint diseases, and many cures were reported as having resulted from injections of this substance. Further trials, however, did not appear to substantiate the claims of the early advocates of the measure, and for a time little was heard of it. But lately the method, in a modified form, has been revived, and several German writers have published reports of cases which would seem to show that it possesses, after all, some merit.

Dr. Wendelstadt, of Bonn, writing in the *Centralblatt für Chirurgie*, September 21, 1889, reports several cases of tuberculous joint diseases in which parenchymatous injections of iodoform-oil were employed with very good effect. At first iodoform in ether was used, but this had to be abandoned on account of the severe pain caused by it. Then the drug was given in olive-oil, one part to five, and was found to cause but little inconvenience. It is important to prepare the mixture each time that it is to be used, as the iodoform soon decomposes and iodine is formed. In some cases a slight rise of temperature was noted after the injection, but this was only temporary. In 85 cases in which the method was employed and in which the results were noted, an apparent cure was obtained in 36, some improvement in 37, while in 12 no benefit was apparent. The writer does not claim that the treatment is in the nature of a specific, but only that it gives good results in most cases. He is probably correct in regarding it as a useful addition to the resources at our command in dealing with this class of diseases, but as one which cannot be relied upon as positively beneficial in all cases.

---

### THE USE OF THYMOL-MERCURY IN THE TREATMENT OF SYPHILIS.

THE analysis of the various secretions of syphilitic patients who are undergoing a course of mercurial treatment has shown pretty conclusively that mercury when given by hypodermic injection is absorbed more rapidly than when exhibited in any other way. Yet the disadvantages of this method are so great that it has failed to find any special favor, in this country at least, where practical availability is more regarded than is theoretical excellence. It is not unreasonable to hope, however, that some preparation of mercury may yet be found whose ready solubility and freedom from irritating properties will render it peculiarly fit for introduction into the system by this often most convenient method.

In the *Archiv für Dermatologie und Syphilis*, September 15, 1889, Dr. Eduard Wellander, of Stockholm, publishes the results of some experiments made by him with the acetate of thymol-mercury. He employed a mixture of one and one-half grain in fifteen of liquid paraffin. The injections were made usually every fourth day, and each patient received an average of six or seven injections. As a rule, the treatment was well borne, and it was seldom that the patients complained of any pain; when this was felt it was usually of very moderate intensity. In one case a small abscess was noted, but it disappeared without causing any trouble. Occasionally a slight induration was noted at the seat of the injection, but in only one case was it so troublesome as to lead the patient to ask for a change in the treatment. Stomatitis was present in a few cases, but this accident happened for the most part in the earlier experiments, when the injections were given every three days, and was much less troublesome when the interval was lengthened to four days. The results were in general very satisfactory, the symptoms disappearing promptly within three or four weeks, although relapses were noted in several instances. In two cases it was found necessary to abandon the injections on account of stomatitis and diarrhœa.

From his experience with this mode of treatment the author concludes that thymol-mercury is much better adapted for injections than is calomel, as it is far less painful and is not nearly so apt to cause abscesses. He regards the method as a great advance in the therapeutics of syphilis, although he admits that the ideal treatment of the disease cannot yet be said to have been discovered.

### THE PHYSICIAN'S FAMILY AND THE PROVISION THAT HE LEAVES FOR IT.

IT is a well-known fact, and as sad as it is notorious, that physicians, even those accounted successful during life, often leave very little behind them for the support of their families. They may have enjoyed a good income, but their expenses were proportionately heavy, and when death overtook them they were found to have laid by little for the future. We do not propose to draw a moral from this, nor to preach the necessity of economy. "As uneconomical as a doctor" is an expression that has become almost proverbial, and preaching will not promote thrift where thrift is impossible. Of course, we do not mean to say that all doctors are improvident, but merely that the lack of a prudent foresight is an all too common failing among the members of our profession. In many cases, moreover, it is impossible to get ahead, the daily income sufficing only to meet the daily expenses, and so, when sickness or death comes and the income ceases, there is nothing left.

It is for this reason that physicians' mutual benefit associations have been formed in many of our cities, and we think it is the duty of everyone to join an association of this kind if he has the opportunity. We say everyone, for the larger the membership of such an association the more benefit is derived from it by each individual member. It is not only the needy who should join it, but the prosperous as well. No one can tell when reverses may come, and it is only the part of a wise man to provide for any possible contingencies. The same argument will apply to life insurance. If a man has his life insured when he is young, the expense is small, and he will have the satisfaction of knowing that his wife and children will not be left destitute, even if he has been unable to lay anything by for their support. Let him first of all join the Physicians' Mutual Benefit Association, if there is one in the community where he lives, and then let him put aside what he can every year in the shape of a premium on a life-insurance policy, and he will not regret it.

If everyone of our readers would but follow this advice, which we assure them is sound, there would be a saving of much suffering to the widows and young children of physicians who have died before their time. The incon-

venience of acting upon this advice now will be slight, but the future misery that will be averted by so doing is great.

---

### ANTISEPTIC TREATMENT OF SMALL-POX.

ALTHOUGH, fortunately, in this country and at this time few practitioners are ever called upon to manage a case of small-pox, the disease is yet by no means so effectually stamped out that we can afford to ignore any advances that may be made in its treatment. In countries where vaccination is generally or universally practised the opportunity to study this disease is, as a rule, too restricted to be productive of any satisfactory results, and we must look, therefore, to other lands than ours for news of progress in this field. Of course there are hospitals in this city, as elsewhere, in which in the course of a year or of a series of years, many cases of small-pox may be seen, but the incentive to study the material there offered is not great, since public interest in the result of such study is but feeble.

There is, however, a country where the question is one of absorbing and perennial interest, and where one may be sure of finding an appreciative audience to listen to any reports of progress made in the treatment of small-pox. This country is Turkey, though throughout the Orient much the same condition prevails, as vaccination is so little practised there as to be almost unknown to the natives in many districts. In Constantinople there is not a physician who is not called upon to treat many cases of the disease every year, and he often sees it in its most dangerous and most loathsome forms. One may readily understand, therefore, that the question of variola and its treatment is not without interest to the resident of that picturesque but insanitary city. It is, of course, among children that the disease works its greatest ravages, since here is to be found the best material for it to act upon, and a large proportion of the mortality of young children is due to this cause.

Dr. Lewentaner, of that city, writing in the *Bulletin Général de Thérapeutique*, No. 32, 1889, speaks very encouragingly of the success attending an antiseptic method of treating the disease which he tried in several cases. This method consisted in the application of an ointment composed of salicylic acid, three parts; starch, thirty parts; and glycerine, seventy parts. The ointment was applied to the face by means of a mask, and also to the other parts on which the eruption was marked. Notwithstanding that the eruption was confluent in many places, large bullæ filled with pus being present, the lesions all dried up without rupturing, and left no cicatrices to mark their site. In addition to this external application, a mixture of quinine in cherry laurel water, oil of sweet almonds, and syrup of orange flowers, was employed. A small quantity of this mixture was dropped on the tongue and back of the pharynx by means of an ordinary medicine-dropper, three or four times an hour. This served to keep the mucous membrane of the mouth and pharynx moist while supplying at the same time a certain amount of quinine. There was about one grain of this drug in one and a half drachm of the mixture.

The advantages of this method of treatment are summed up by the author as follows:

1. All the children treated in this way recovered, although the ordinary mortality of the disease is forty per cent.

2. The duration of the disease was decidedly shortened, the period elapsing from the commencement of the eruption to the falling off of the crusts being twelve or thirteen days.

3. The disease ran its entire course almost without fever.

4. The danger to those around the patient is greatly lessened. In the author's cases there were other children exposed, but notwithstanding that they were not vaccinated, they did not contract the disease.

5. The simplicity of the method, as compared with the treatment by baths and cold applications, has much to recommend it.

6. Æsthetically, also, the antiseptic method of treatment offers great advantages, since it prevents absolutely all pitting.

---

### THE PATHOGENIC PROPERTIES OF MICROBES FOUND IN TUMORS.

M. VERNEUIL, of Paris, is not much known as a bacteriologist, but with the help of Dr. Nepveu, who does possess skill in this line, he has been studying the bacteriology of tumors with some interesting results.

Neither Verneuil nor Nepveu find that there are any specific microbes causing cancer, sarcoma, fibroma, etc., but they do find these tumors are often the seat of various pathogenic organisms which may and do infect the system, causing fever, phlegmonous inflammation, sepsis, etc.

It has been observed that sometimes after the ablation of a tumor, despite all ordinary antiseptic precautions, there develops a sudden septic infection, or fever. This accident is due, according to Verneuil, to the fact that the tumor contained in certain parts, or in its juices, pathogenic organisms which infected the wound. It has happened that after tapping an ovarian cyst the patient rapidly becomes prostrated and dies; the bursting of a cyst or its accidental breaking has seriously complicated the progress of the case. Verneuil contends that there are microbes or microbic poisons in the cystic fluid, and that these cause all the trouble. He has made some experiments to prove this point. Fluid from cysts was withdrawn and injected subcutaneously into four dogs. They all died in two to eight days, with septic symptoms.

Verneuil's conclusion that microbes and microbic poisons are often associated with malignant tumors is one that is *a priori* very probable, and one belief in which clinical experience confirms. His investigations teach, he thinks, that malignant growths should be extirpated as soon and as thoroughly as possible.

---

### THE "CORN-STALK DISEASE."

ALREADY the pathologist and the student of the ultimate sources of disease have found in the study of the maladies of animals an interest and a profit fully equal to that which proceeds from the investigation of human disease-changes. The articles of Frank S. Billings, in the *Buffalo Medical and Surgical Journal*, July to October, 1889, upon the "Corn-stalk Disease in Cattle," are good specimens of the scientific work which is now going on in this department of medicine.

The history of the epidemic is in each instance about as follows: In late autumn or winter, cattle are turned into fields of Indian corn, from which only the ears have been removed, or which has been "topped," to clean up the remnants of leaves and tops, and stalks, if they will eat the latter. After a few days one and another of the cattle is taken ill with a malady which may cause death in from twenty-four hours to ten days, or may result in recovery. It is an acute blood-poisoning, with fever from 102° to 107.6° F. There is weak pulse and rapid respiration. The animal may either bellow and chase other animals—as dogs, hogs, and fowls—or may stand by itself apart, depressed, and loth to move. All the sick retain the power to swallow, and all drink. There is frequently constipation, which may in favorable cases turn to diarrhœa. The urine appears normal. There is yellowish-red congestion of mucous surfaces. The secretion of milk slackens or ceases. The post-mortem macroscopic changes are those of acute septic febrile disease. The disease is not conveyed by one animal to another.

The farmers were sorely puzzled. Only certain fields or parts of fields were dangerous. They could never tell when a valuable herd would be decimated, if turned into a fodder-field. Various theories, easily disproved by experiment, were prevalent among farmers. It was held to be caused by lack of salt and water for the cattle; by dryness of the fodder; by smut (*ustilago maidis*); but it was seen in cattle which had water and salt; and the dry-food theory was shown to be false. Moreover, cattle fed on large quantities of smut were not made ill.

The growing corn was now examined. In the diseased patches the plants were stunted, if attacked in early summer. The lower leaves die, becoming yellow, with colored streaks. The roots decay in the ground, even the brace-roots becoming corroded. The ears do not mature.

Microscopic examination of the leaf-streaks and other diseased parts reveals the presence of an organism which is now believed to be the cause of the disease. It is never found far from parts which are plainly diseased, and it invades the healthy tissues at the edges of the affected areas.

The germ resembles very closely that of the Southern *cattle plague* of *wild-seuche*, and of the swine plague. It is ovoid, its length being about one-sixth the transverse diameter of a red blood-cell. When stained it resembles a small white bean, with both ends and two sides stained. It moves by a sort of rolling action. Dr. Billings supposes that the white, non-coloring substance is a secretion of the two poles or coccoid ends, and that it may constitute the ptomaïne or essential poisonous pathogenic principle of the disease, which gets into the fluids of the animal body by the breaking up of its capsule, which occurs as the germ becomes mature.

These organisms have been cultivated in media outside the body, and the injection of the cultures into animals has produced symptoms of "Corn-stalk Disease."

It is not known whether grasses and other grain-plants are affected by the disease. It is probable that the grains of the corn-ears may be diseased as well as the plant itself.

The diagnosis between the corn-fodder disease and the other diseases in which similar micro-organisms are found, is quite easily made by the history. It is most like the swine plague, but swine are not subject to it.

The only treatment suggested is the early administration of Glauber's salts, to clear out the intestines, and reduce the febrile congestion of affected organs. Methods of prophylaxis readily suggest themselves, including destruction by fire of all discharges, and of all corn or other plant-matter supposed to contain the germs of the disease. Animals killed by it should be immediately burned.

The disease is found in many States, especially of the North and West. It may attack horses, sheep, and goats, though generally seen in the cow. It is said to cause greater loss in cattle to the farmer of the great corn-raising States of the West than all other causes combined.

---

### DOCTORS AS BEGGARS.

THE physicians of Chicago are trying, we are told, to establish a public library for the benefit of the profession. They first tried to get the City Library to make sufficient provision for their wants, but failed; and they had equally poor success with the trustees of the new Newberry Library. Now the doctors have ceased trying to get other people to give them a library, and are taking hold themselves. Already $10,000 has been raised. We commend the spirit thus shown, and trust that our brethren by the lake will succeed in getting a great library. It is a good plan for the profession to take care of itself just as much as it can. We have always heretofore looked to outsiders for help in building hospitals, colleges, laboratories, and libraries, with the result that the doctor in most of these institutions is but a minor factor in their management. The medical profession deserves public help in its purely scientific and benevolent work; but it can do a great deal more for itself than is sometimes supposed.

---

## News of the Week.

THE METAPHYSICAL COLLEGE OF MASSACHUSETTS, an institution for teaching Christian Science, has dissolved.

ONE OF THE BEST AGENTS TO ABORT A CORYZA, according to Dr. Beverley Robinson, is carbonate of ammonia, in frequently repeated and rather large doses.

DR. WILLIAM COCKCROFT, of this city, died on November 18th, in the seventy-second year of his age.

A DEATH has been reported following the use of two fifteen-grain doses of sulphonal, the doses being given an hour and a quarter apart. The fatal result occurred forty hours after the first dose. The patient was a woman with melancholia, aged twenty-eight. The mode of death was apnœa.

THE BEST ANTIDOTE TO CARBOLIC-ACID POISONING is soap, which should be taken at once and repeatedly.

CREOLIN is being used to the exclusion of other antiseptics in the Obstetric Department of the Frauen Klinik under the care of Professor Winkel, of Munich.

THE BEST LOTION for recent injuries, says Billroth, is the ordinary lead lotion.

DR. ROBERT GAMBLE CABELL, a prominent physician of Richmond, Va., died last week, aged eighty.

A Chicago Doctor has sued Miss Frances E. Willard, President of the Women's Christian Temperance Union, for $50,000, for some trouble connected with the jurisdiction over a hospital managed, or sought to be managed, by the Union.—*Boston Medical and Surgical Journal.*

Politics and Charity.—The Associated Charities of Denver have opposed the building of a hospital by the city, because of the danger that the management of a hospital under the government of the city might be subjected in an injurious way to political influence.

New York Post-graduate Medical School and Hospital.—The Executive Committee of this institution have established a clinic for diseases of the rectum, to be under the care of Dr. Charles B. Kelsey, for the treatment of poor persons suffering from these diseases.

Dr. Francis J. Quinlan of this city was recently appointed Lecturer on Diseases of the Throat and Nose in the New York Polyclinic School and Hospital.

The Middleton Goldsmith Lecture.—Professor William Pepper, Provost of the University of Pennsylvania, will deliver the Middleton Goldsmith Lecture before the New York Pathological Society, in the hall of the New York Academy of Medicine, on Wednesday evening, January 15, 1890. The subject of the lecture will be "Hepatic Fever."

Dr. Thomas H. Burchard, of this city, gave a dinner at his residence on Monday evening, November 18th, to Dr. Blanc, of Aix-les-Bains, France. A select number of representative medical gentlemen were present. A phonograph was on exhibition, enlivening the occasion by songs and instrumental music. Dr. Burchard welcomed the guest of the evening, and Dr. Blanc gracefully replied, after which the phonograph recorded a characteristically eloquent welcome from Dr. Lewis A. Sayre; and thus will the coil echo his voice, tingle the ears, and warm the hearts of his many friends across the sea.

Dr. Charles A. Powers has been appointed Assistant Surgeon to the New York Cancer Hospital.

Another Hospital for Chronic Invalids, to be called the Isabella Heimuth, will soon be opened in this city. It is non-sectarian.

The Late Dr. Ricord, like many other eminent physicians, was a most benevolent man, but lacking in business capacity. When the Empire came, it brought him royal favors, wealth, and academical distinction; but notwithstanding his large income, which probably exceeded that of any other French doctor of the time, Ricord was constantly falling into debt, owing to his charitable disposition. He not only attended poor patients for nothing, but actually fed and housed them, and in the case of country or foreign patients he often paid their expenses to Paris. He was several times sold up, and even sent to prison while imprisonment for debt was possible. He was released by the Emperor, who paid his debts.

An Antiseptic Ointment, certain in power and not unpleasant in odor, is often desired, not only by the obstetrician but also by the gynecologist. Dr. Th. Parvin says that benzoated lard, to which four per cent. of creolin is added, will meet these indications satisfactorily.—*College and Clinical Record.*

"Vaso-motor Centre-itis" is the cause of puerperal eclampsia when there is no albuminuria or renal trouble to explain the convulsions. Such, at least, is the opinion of Dr. A. D. Macdonald (*Medical Press and Circular*), and he is certainly to be congratulated for giving us so rhythmical an addition to polynymy, as well as in attaching an actual anatomical disorder to a purely physiological centre.

Fire at the Faculté de Médecine.—The fire in the grand amphitheatre of the Paris Faculty of Medicine caused damage to the extent of some £2,800. Three immense pictures by Matout were destroyed. One of them represented Ambroise Paré applying a ligature for the first time, and was valued at £400. Of the two others, one represented the first clinical lecture in surgery at the Hôtel Dieu, and the other the first lecture on physiology at the chapel of St. Julien le Panore. The bust of Hippocrates, which has been gazed upon by so many generations of students, was also destroyed.

The Surgery of the Liver.—Mr. Lawson Tait, writing upon "Surgery of the Liver" (*Edinburgh Medical and Surgical Journal*), says: When first I attacked the liver by surgical operation I certainly was in terror of hemorrhage, for I thought that if an incision opened a large sinus the arrest of hemorrhage would be a matter of considerable difficulty, but I was encouraged by an accident which befell me in performing an ovariotomy, for there, on undoing an adhesion to the liver, I tore a cleft in the free edge of the organ, certainly an inch and a half deep, which bled freely, and I was greatly alarmed; but I took a small piece of solid perchloride of iron about the size of a pea and rubbed it over the edge of the tear. The hemorrhage stopped immediately, and my patient made an easy recovery, so that my respect for the liver greatly diminished. On one occasion I did open by my incision a sinus of considerable size, but I passed a thread by means of a fine needle down one side of it and up the other, and tied the sinus between the two limbs of the ligature. In this way the hemorrhage was arrested, and I heard nothing of the ligature. I was also in fear of another condition which, *à priori*, one might have expected —that it would be difficult to stitch the edge of the wound of a friable organ like the liver to the abdominal wall, and that the stiches would be very likely to give way. As a matter of fact, I have not found it so, and in not a single instance has this given trouble. In my operations upon abscesses of the liver all the cases have recovered but one.

The Russian Academy of Sciences offers a prize of 5,000 roubles ($2,500) for the best inquiry into the nature and effects of the poison which develops in cured fish. The competition is open to all. The memoirs must be sent in, either in manuscript or printed, before January 1, 1893, and may be written in any one of the following languages: Russian, Latin, French, English, German.

Pæderasty in Aristocratic Circles.—A loathsome scandal has occurred in London. A number of depraved members of England's aristocracy took a house in a fashionable part of the city and hired boys to assist them in the gratification of perverted and criminal sexual indulgence.

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON SURGERY.

*Stated Meeting, November* 11, 1889.

ROBERT ABBE, M.D., CHAIRMAN.

#### RESULT OF SUTURING THE TENDON OF THE QUADRICEPS FEMORIS.

DR. W. T. BULL presented one patient, and said he had expected another, both illustrating the result of suturing the tendon of the quadriceps femoris. The first case had been made the subject of a paper read before the Surgical Society, but he had not had an opportunity to show the patient in illustration of the result, which was satisfactory union of the subcutaneously ruptured tendon and complete restoration of the functions of the joint. The boy presented was aged seventeen, and was admitted to the hospital in April last with a wound one and three-quarters of an inch in length above the patella, made by a circular saw. The tendon of the quadriceps had been cut directly across immediately above the patella. An incision was made three inches in length from the patella upward, and the tendon was sutured with catgut, the joint drained, and knee enveloped in an antiseptic dressing. There was at no time any suppuration, and the patient went about the wards with a plaster-of-Paris splint at the end of ten days. At the present time the power of extension had become normal, and the joint movement free.

In such a case as this, he said, in which there was an open wound, no one would hesitate to suture the divided tendon, but in other cases in which the rupture was subcutaneous the question of whether it was best to cut down and suture, or to leave the ends to unite without such operation, had not yet been settled. In view of the good result in his first case he would be disposed to operate.

#### SUTURE OF THE RUPTURED PATELLAR TENDON.

DR. R. G. WIENER presented a man who had been operated upon five years ago by Dr. Sands for rupture of the patellar tendon, with a perfect result. In December last the man fell down-stairs and ruptured the tendon again. He was transferred to Dr. Wiener's service at Charity Hospital in June last. He found the patella about four inches above the joint-line; power of extension entirely gone. He made an incision nine inches long over the joint, but found no remnants looking like patellar tendon. He then tried to use tissue on the lower part, shaping it somewhat like the tendon, but was unable to draw the patella down, and consequently was obliged to make complete section of the quadriceps tendon. Then, in order to bring the bone to its place, he had to drill and wire the patella and tibia, and then suture together the remains of the tendon on the two bones. Primary union took place, and the patient left the hospital at the end of three months, able to walk on the leg.

#### DOUBLE FEMORAL HERNIA IN A BOY.

DR. MILLIKEN presented a boy who had a double femoral hernia, the chief interest of which centred in the rarity of the affection before the twentieth year of age. Statistics showed only about one per cent. of hernia in that locality in men before the twentieth year.

#### COLO-COLOSTOMY.

DR. WILLY MEYER presented the woman on whom he operated forty months ago for cancerous stricture of the large intestine, and whose history was published in THE MEDICAL RECORD. The patient was still healthy in appearance, was stewardess on an Atlantic steamship, and weighed one hundred and fifty-one pounds, being only four pounds less than what she weighed a year ago. Yet hard masses could he felt, showing an extension of the malignant process. This was the first case of which he knew in which intestinal anastomosis had been successfully performed between two parts of the colon.

#### LARGE VASCULAR SARCOMA OF THE NECK, OF FIFTEEN YEARS' DURATION.

DR. F. S. DENNIS presented a man from whom he removed a vascular sarcoma of the deep structures of the neck, of the size of a child's head, three weeks ago, the tumor having been present fifteen years. Usually these sarcomata terminated fatally inside of two years. The growth in this case extended beneath the carotid and up to the base of the skull.

#### DRAINAGE OF THE KNEE FOR ACUTE SUPPURATIVE RHEUMATISM.

Dr. Dennis also presented a man who was transferred to the surgical ward from that of Dr. Janeway in Bellevue Hospital, where the diagnosis had been made of acute articular rheumatism affecting the knee, which went on to suppuration. Suppuration also took place behind the joint and below. The patient had a temperature of 103° F., with chills. Dr. Dennis opened the joint freely in three places, and inserted drains. Fully a quart of pus escaped. The patient was going about, and had a fairly useful joint, although he had not yet attempted to move it much.

#### PARALYSIS OF THE ARM AND SUBLUXATION OF THE SHOULDER-JOINT FOLLOWING AN INJURY.

Dr. Dennis presented a boy for diagnosis. About three months ago he fell from a horse and was supposed to have dislocation at the shoulder, which was reduced. When presented there was complete loss of motion in the arm, and of sensation anteriorly, and what Dr. Dennis believed to be subluxation of the shoulder-joint. Had there been a tearing of the brachial plexus at the time of the injury, or fracture of the coracoid process permitting of subluxation of the humerus, while the nerves afterward became involved in the inflammatory process? He thought of cutting down and learning the exact condition present.

DR. KAMMERER remarked that during the summer he had seen several cases of sarcoma of the neck, and had found them even more malignant than sarcoma of bone.

DR. C. A. POWERS said the last case presented by Dr. Dennis showed apparently exactly the same features seen in a woman at the Chambers Street Hospital two years ago. Dr. Dennis' patient, he thought, had atrophy of the deltoid, relaxation of the capsular ligament, and the slipping down of the head of the humerus was due to that fact. He did not think the head of the bone left the glenoid cavity entirely.

DR. A. G. GERSTER said he had repeatedly seen paralysis of the nerves composing the brachial plexus following dislocations of the shoulder-joint and fractures of the humerus, which had taken place in the vicinity of the shoulder-joint. He then recalled four cases in which that symptom was observed, and in all, as subsequent events proved, the paralysis was traumatic, so called, due to direct injury or inflammatory changes following it. In all, the function of the nerves was recovered. In a boy there was fracture of the neck of the scapula, which could still be demonstrated after restoration of nerve-function had taken place a year and a quarter subsequent to the accident. In the case presented he did not believe the plexus had been torn, and he thought it best to wait, submitting the boy to such treatment as was known to hasten restoration of function in disabled nerves, and if not successful at the end of a year, cut down and unite the divided nerves if that was the lesion present. He did not think there was dislocation of the humerus, but simply a relaxation of the tissues which held the head of the humerus in the socket. As Dr. Powers had remarked, the head did not go into the axilla.

With regard to the case of knee-joint disease, he thought it might have been one of acute infectious osteo-myelitis located near the joint, perforating into it, causing acute

suppuration of the knee. The fact that abscesses were found in the leg simultaneously with pus in the joint would seem to favor that assumption. It was extremely rare to find pus in joints affected by acute articular rheumatism. It was oftener present in the gonorrhœic form, but even in such cases it was not pure pus, but rather a sero-purulent liquid. He did not remember ever to have seen a case of acute rheumatism result in acute suppuration of a large joint.

Dr. R. F. Weir said the result in Dr. Dennis' case had been so much better than he had seen in his own or other surgeons' treatment of chronic suppurative synovitis that he thought it might be well to speak of Mr. Treeves' method, which was somewhat similar, and gave like good results. Mr. Treeves showed him several cases treated for suppurative synovitis, and motion had been well preserved. The treatment had consisted mainly in opening the joint and in continuous irrigation, plain water being allowed to trickle through the joint continuously several days.

Dr. Dennis said the irrigation in his case was kept up from time to time not longer than twenty-seven days.

The Chairman thought that if injury of the nerves was to be sought for in the boy's case, it should be nearer the spinal processes.

### EXCISION OF THE RECTUM FOR CANCER BY KRASKE'S METHOD.

Dr. Arpad G. Gerster presented a Hebrew laborer, on whom he performed excision of the rectum for cancer, February 17th last. Besides subjective symptoms, examination showed a rather irregular, nodular tumor, occupying the lower portion of the rectum and extending as high as the finger could reach. The sphincter was also involved. Kraske's method was adopted, consisting in first removing the coccyx and part of the sacrum in order to get at the rectum. The amount of the gut removed was about five inches in length. The difficulty of such an operation was very great by the ordinary method, while it was very easy after taking away a large portion of the sacrum, making the parts readily accessible. One could easily control hemorrhage, and take the necessary precautions, when the peritoneum was invaded. He thought the method was not only valuable in operations for removal of the cancerous rectum, but also in removal of the cancerous uterus, etc.

In July he noticed a suspicious nodule near the margin of the anus, which he removed, and drew the stump of the rectum farther down. He again loosened its attachments on another occasion, and drew it still farther down. The man now had a sphincter which enabled him to retain both hard and soft fæces.

Dr. F. S. Dennis then read a paper (see p. 566) entitled

### FRACTURES OF THE BASE OF THE SKULL.

Dr. R. F. Weir doubted the statement that in most cases of fracture at the base of the skull death took place from conditions known to arise from infection. In most cases where death ensued it was from the primary effects of the injury, and took place within twenty-four hours. He cited a case in which there was a discharge of clear fluid from the ear for some time, with loss of hearing, but absence of hemorrhage and coma. In the New York Hospital, when hemorrhage took place from the ear, they washed it with an antiseptic fluid and introduced iodoform gauze and cotton, but they did not resort to the head cap described by Dr. Dennis, although it might be an extra precaution worthy of adoption. He once tried to render the nasal cavity aseptic by plugging, but when he reflected on the conditions there present he gave it up as practically impossible.

Dr. A. G. Gerster said he had felt from the beginning, when listening to the paper, that he could stand with Dr. Dennis in the support of cleanliness and antiseptic precautions in fractures at the base of the cranium when such fractures could be considered compound. Sometimes, however, the fracture was simple, not compound, and even this form might result in suppuration. In other words, that suppuration might occur without communication with the air, and consequently in spite of antiseptic precautions. But he did not mention these facts as vitiating the soundness of the principles of treatment laid down in the paper. The necessity for antiseptic precautions was shown in a case at the Mount Sinai Hospital nine years ago. A man came who had hemorrhage from the ear three days. The hemorrhage ceasing, the house surgeon discharged him without any antiseptic precautions. He was afterward brought back with meningitis, and died. The post-mortem showed fracture at the base, rupture of the drum-membrane, and purulent otitis which had communicated with the base of the cranium. Antiseptic precautions might have prevented the otitis, and consequently meningitis and death. He doubted, as Dr. Weir had done, whether the nasal and oral cavities could be disinfected and kept so any length of time. He thought a dressing covering the ear, temporal and mastoid regions, and below, might take the place of the cap, and in the case of ladies it might be necessary to spare the hair.

Dr. John A. Wyeth thought it might be well to try drainage in case of fracture at the base by drilling into the skull, as had been practised in one case of fracture of the frontal bone, the surgeon establishing drainage by drilling into the ethmoid.

Dr. Dennis, in closing the discussion, said the simplest way to keep the head clean was to shave it; the hair would grow again. Regarding drainage, in fracture at the base, it was already present and he thought we needed simply to keep the parts aseptic. He still thought a plug of cotton would prevent infected air from passing up into the upper chambers of the nose and thus gaining access to the cranium.

### SIMPLE FRACTURE OF THE CARPAL SCAPHOID.

Dr. C. A. Powers presented the specimen, which had been removed post mortem. It had the evidences of recent fracture, without injury of the skin. But three cases of simple fracture of the carpal scaphoid were on record. He believed it was impossible to make a diagnosis of the condition without an exploratory incision.

Dr. F. Kammerer read a paper (see p. 569) entitled

### OPERATION ON A SARCOMA OF THE DURA MATER, AND LIGATURE OF THE LONGITUDINAL SINUS.

Dr. Weir said he had twice ligated the longitudinal sinus for hemorrhage. In one case the ligation was to control hemorrhage from a gunshot wound received in the war. The patient died, but the ligation had nothing to do with death. The other case was that of a child with fracture of the vertex; in applying the trephine, he got too near the median line, wounded the longitudinal sinus, ligated it, thus controlled hemorrhage, and the patient recovered.

---

## AMERICAN RHINOLOGICAL ASSOCIATION.

*Seventh Annual Meeting, held at the Palmer House, Chicago, Ill., October 9, 10, and 11, 1889.*

### Wednesday, October 9th—First Day.

The Association was called to order at 10 A.M. by the President, Dr. John North, of Toledo, O.

The following were elected Fellows of the Association: Dr. E. L. Siver, Fort Wayne, Ind.; Dr. C. L. Dreese, Goshen, Ind.; Dr. O. F. McGahan, Chattanooga, Tenn.; Dr. Ely McClellan, Chicago, Ill., and Dr. L. B. Gillette, Omaha, Neb.

The next thing in order was the President's Address, which dealt, 1, with the relations that the physician bears to the public; 2, the relation of the specialist to the general practitioner and other specialists, and, 3, what the American Rhinological Association has done for the public and for the profession.

Dr. L. B. Gillette, of Omaha, read a paper entitled

REPORT OF A CASE OF BRAIN ABSCESS EMPTYING INTO THE NASO-PHARYNX.

The patient, aged twenty, farmer by occupation, strong and healthy, while working on an embankment in September last with a wheel-scraper, in driving along with it loaded, it in some way became unlatched and the handle, in flying up, struck him forcibly under the chin, knocking him down a sixteen-foot embankment, where he lay unconscious for thirty minutes. A week afterward he noticed that something was wrong with his eyes. About October 15th he went to work in a brick-yard, worked three days, and then complained of being nervous and of having a slight headache. On the evening of the third day he got soaking wet in a rain, went home cold, had a chill, followed by fever. A physician was called and pronounced it malarial fever. Dr. Gillette being subsequently called to see the case found the patient suffering with intense headache, the pain extending down between the shoulder-blades, and particularly into the right arm. Both pupils were widely dilated. Temperature was 101° F.; pulse, 105. He knew he had an inflammatory condition to deal with. A day or two after his advent into the case there developed marked compression of the brain. Temperature went down to 96°; pulse as low as 42; respirations to 9 or 10. Complete paralysis of right side and partially of left; complete loss of sensibility as well as of consciousness. He also lost the sense of sight, and remained in this condition four days without any perceptible change whatever. The patient took his food and medicine regularly. He was surprised one morning on finding that the patient had much improved. The mother told him that during the night the patient had a violent attack of coughing and showed him the character of the sputum. It was about an ounce of green, stinking pus, mixed with mucus. From this time the patient began to improve. There was an immediate return of consciousness, a quickening of the heart's action and respirations. Examination of the throat showed that the pus came from above. No pus came out of the Eustachian orifices, and when the patient leaned forward it would come out of the anterior nares. The discharge lasted two weeks. Where it came from, or how it got through, he could not tell. His opinion favored the ethmoidal and sphenoidal sinuses. As a result of this terrible ordeal the patient, when seen three months since, was totally blind, sense of hearing lost in right ear, has not got the use of his right arm, and his mind is not what it was. Could such results take place without some destruction of the brain-tissue proper? Could the patient have the same results from an intra-meningeal accumulation?

In the treatment Dr. Gillette used opium, quinine, mercury, cold applications to head, and cupping at the back of the neck, and the triple bromides as they were indicated. As soon as marked compression of the brain had developed he began to use eighty grains of iodide of potash each day, and kept it up for thirty days. Did this treatment have anything to do with the results?

Dr. Thomas F. Rumbold, of St. Louis, read a paper (see p. 570), entitled

FIVE REASONS FOR FAILURE IN TREATING CHRONIC RHINITIS.

The first is defective instrumentation. Not one of the physicians whose offices he had visited had a tongue-depressor that would not cause the patient to retch as soon as it was introduced into the mouth. The blades of all the instruments he saw were too wide to go between the teeth, and too long, being about six inches in length. These instruments were seldom used in examinations, the exceedingly defective method of drawing the tongue out with a napkin being employed instead.

2. The spray-producers used were made for watery solutions only. These physicians did not possess an instrument that could throw warm vaseline. Liquid cosmoline was found in every office. While this remedy is far superior to tannin, iodine, nitrate of silver, or any of a dozen other agents commonly found in offices, yet it is much inferior to warm vaseline.

3. The compressed air used was taken from a container of a capacity of from three to four or five gallons. Air enough was forced into this reservoir to show a pressure of from thirty to seventy pounds. The reservoir was filled by an air-pump whose barrel was made of brass; the piston was packed with leather, which is partially decomposed animal tissue, and it was lubricated with rancid oil of some kind. Ten pounds is the greatest pressure that the mucous membrane can stand without producing irritation, while by far the greater majority of patients require from six to eight pounds pressure only.

The fourth reason for failure was an anatomical one. He meant by this an error in locating the disease. Innumerable clinical observations and post-mortem examinations prove conclusively that rhinal inflammation invariably commences on the superior and middle turbinated processes and extends in all directions in the nasal passages and into the passages connected with them, except on the floor of the nasal passages or so-called inferior meatuses. These two portions are seldom affected with inflammation.

Keeping in mind that every irritation produces inflammation, what are the indications for treatment of chronic rhinitis?

*a.* The diseased secretion, which is always acrid, therefore irritating, should be removed. If morbid growths are present, as these also are irritating, they should be removed, thus removing the local sources of inflammation.

*b.* The new secretion, that is, that which is to be formed upon the surfaces that have been cleansed, should be prevented from becoming acrid, thus preventing another cause of inflammation.

*c.* Hygienic and sanative measures should be insisted upon. This is to prevent a continuance of the irritation to the sensory nerves that are located upon the surface of the body and mucous membrane, by colds and other irritating agents, thus removing the originating causes of the inflammation.

Dr. A. De Vilbiss, of Toledo, in opening the discussion, differed from Dr. Rumbold in that he did not believe properly tanned leather readily decomposes. Rancid oil for lubricating the air-pump is hardly ever used. Personally he used vaseline and naphthol as an application to the mucous membrane. With regard to vaseline it was used as a protector to the mucous membrane on account of its density.

Dr. O. F. McGahan, of Chattanooga, heartily concurred in what Dr. Rumbold had said regarding vaseline. Where we want the surface protected nothing will better take the place of vaseline. He sometimes uses iodine in weak solutions, and has not as yet had any bad effects from it.

Dr. A. G. Hobbs, of Atlanta, used the oil of vaseline. First, for cleansing purposes, and, second, for its celerity. He can warm it much quicker than the solid vaseline. The danger and greatest objection to the douche in cleansing the nasal passages is its liability to set up middle-ear catarrh, which is sometimes produced by the post-nasal and anterior nasal douche.

Dr. John North, of Toledo, did not favor the use of tongue-depressors. Patients should be trained to manage their tongues without them. When he did use one it was a small wire tongue-depressor. He uses the oil of vaseline for cleansing the nasal passages, with a little alkaline spray or even with eucalyptus or some other antiseptic dissolved in it. High pressure the rhinologist did not want.

Dr. C. L. Dreese, of Goshen, Ind., read a paper on

REFLEX SYMPTOMS OF RHINAL DISEASES, WITH REPORTS OF CASES.

The first case was one of heart, stomach, and lung troubles caused by sympathy from rhinal disease. The removal

of the latter affection was followed by recovery of the former. The second case was one where incontinence was a reflex symptom of chronic nasal catarrh, and was cured by treating the catarrhal trouble alone. The third was one in which epilepsy was a complication of rhinal disease.

Dr. C. H. Moore, of Indianapolis, contributed a paper on

OCULAR REFLEX SYMPTOMS IN NASAL DISEASES.

He had relieved a case of neurotic affection of the Eustachian tube of the left ear by spraying the nasal passages with vaseline. Hack mentions a number of cases of hemicrania and asthma cured by the galvano-caustic destruction of the hyperplasia of corpora cavernosa of the nasal cavity. Voltolini demonstrated that asthma may be relieved by the removal of nasal polypi. A certain group of eye symptoms, such as lachrymation, photophobia, conjunctival hyperæmia, are observed in a number of patients that come to the rhinologist, and yet the examination of their eyes reveals no anomaly. The vision is normal, no eye strain, conjunctivæ healthy, the puncta lacrymalia favorably placed, and the tear-ducts open. For such cases a simple eye-wash has been ordered, cold or warm applications recommended, general hygienic treatment advised, without any relief to patients. Relief of the rhinal affection in these patients was generally followed by a cure.

The cases he reported had the following symptoms in common:

1. Burning and smarting sensation of the eyelids, especially in the morning.
2. Difficulty in distinguishing an object in ordinary daylight.
3. Increased vascularity of the conjunctiva and lachrymation on exposure to the air.
4. The sound condition of the eyes and their appendages.
5. Failure of ocular and general treatment.
6. The efficiency of nasal treatment.

Dr. N. R. Gordon, of Springfield, Ill., said his rule of proceeding with such cases is to examine the eyes for irritation or the condition of refraction, and if the latter is normal, and no other source of inflammation can be found in the eye, he examines the mucous membrane of the nasal passages, and very often the cause is to be found there.

Dr. E. R. Lewis, of Indianapolis, said there was no doubt but that a number of such cases are being constantly referred to the rhinologist. It should be determined that there is no error of refraction requiring treatment before the rhinologist accepts the case. About one-third of his cases were sent to him by Drs. Thompson and Stillson (oculists), but not until the eye trouble had been corrected, after which he commenced to treat them for rhinal troubles. This he believed to be the logical course to pursue in such cases.

Dr. E. Fletcher Ingals, of Chicago, related the case of a lady which illustrates the possibilities of eye trouble being caused by nasal disease. She came to him with hypertrophic rhinitis. He proceeded to cauterize the turbinated bodies, and before she left the office she asked him if he could not do something for her eyes, that she was unable to use them more than five minutes at a time for the last three years. He referred her to an oculist that she might get relief. She did not return to his office for two weeks; on her return she said she had not been to an oculist, but that the next day after the nose had been cauterized she was able to read at night and it did not affect her eyes.

Dr. N. R. Gordon read a paper on

THERAPEUTIC MEASURES IN RHINOLOGY.

He said that after the surgical removal of hypertrophied tissue a curative local treatment, continued at short intervals for one or two years, or even longer, is necessary. This should consist of the oil of vaseline, with a small amount of eucalyptol or something of that character. Astringents do but little, if any, good. Where the oil of vaseline fails, salt and water in proper proportions, with a small amount of Listerine, or Dobell's solution, are suitable remedies. To prevent mouth-breathing during sleep, he recommends his patients to wear a little instrument made of celluloid, that fits nicely between the teeth and lips.

In atrophic catarrh, after the removal of all secretion on the surfaces, where the mucous membrane is very thin or even ulcerated, he finds the application of a solution of resorcin, one drachm to the ounce, to be exceedingly beneficial. In the most unyielding and obstinate form of nasal catarrh he uses a glycerine suppository composed of ninety-five per cent. glycerine and five per cent. stearin. The solidified glycerine is placed so as to come in contact with the atrophied or ulcerated portion of membrane. The glycerine soon asserts its well-known affinity for water, and the result is an abundant flow of thin mucus.

---

Thursday, October 10th—Second Day.

Dr. C. H. Von Klein, of Dayton, O., read a paper entitled

ATROPHY, HYPERTROPHY, AND DEVIATIONS OF THE SEPTUM,

in which he said he had examined the nasal cavities in over six hundred patients, and found not exceeding two per cent. to have an absolutely straight division of the nares. In almost every case he observed deformities of some sort, either atrophy, hypertrophy, or deviation of the septum.

The causes which are most common to deviation of the septum occur to people when they are in their babyhood. When children commence to creep and walk around, passing from chair to chair, they fall, and nine times out of ten it is on their nose. Personal observation leads him to believe that atrophy of the septum is confined to the cartilaginous portion. Hypertrophy, on the other hand, is confined to the osseous portion of the septum, and these conditions are generally caused by such injuries as may occur to any other part of the bony system. A stroke or fall on the osseous portion of the septum may produce hypertrophy.

Dr. C. F. McGahan, of Chattanooga, read a paper on

THE TREATMENT OF CHRONIC NASAL CATARRH,

in which the author said the remedies for its treatment comprise almost the whole materia medica. Formerly it was treated principally with strong astringents—for example, strong solutions of nitrate of silver by the post-nasal syringe, sprays of tincture chloride, tannic acid, etc. Where we have polypi the first thing to do is to remove them, which can be done by the snare or the galvanic cautery. Where the polypi are located in the anterior chamber he prefers the cautery; but when they are in the posterior chamber of the nose, the snare. Acids he did not like in the treatment of hypertrophies, as it is impossible to control the exact amount of tissue they will destroy, and then the pain is always more intense than after the use of the cautery. The hypertrophy being reduced we have simply a case of chronic catarrh with moderate hypertrophy to combat.

At the outset we should spray the nasal cavity thoroughly with Dobell's solution, or the combination with Listerine, which is recommended by Leffert. Seiler's tablets are convenient and effective. He has the spray tubes of Sass, Rumbold, Davidson, and Richardson in his office, but prefers the DeVilbiss, for with one of the DeVilbiss make for aqueous fluids, and another of the same make for oils, the rhinologist can apply nebulæ to any part of the nasal cavity. Having cleansed the nasal cavity thoroughly we are now ready to apply our medicament. When there is moderate hypertrophy he generally used about three times a week a spray of vaseline with a combination of the iodides, or with iodine and carbolic acid.

The liquid albolene (as manufactured by McKesson & Robbins) is by far the nicest vehicle he had as yet used, although it does not remain upon the tissues as long as vaseline, and when used for its protective effect the vaseline was preferable. He now uses the iodine and iodides dissolved in albolene, first as a spray for their alterative effect, and then spray in just pure vaseline to protect the tissue from air or any particles that may be suspended in the air. After cleansing the nasal cavity thoroughly, he usually sprays the parts with vaseline combined with a few drops of eucalyptol or oil of gaultheria, sometimes a drop of carbolic acid to the ounce of vaseline. On account of the hydragogue effect of glycerine upon the tissues it occurred to him some time ago that in hypertrophic conditions of the nasal cavity it may be useful in drawing the water from the tissues and thereby reducing them in size. He had often seen it advised in combination with other drugs in the different sprays, but his way of using it was similar to that of the gynecologists when they apply it on tampons for different hypertrophic conditions of the uterus. The cavity having been thoroughly cleansed he applies to the hypertrophic membrane a tampon soaked in a solution of glycerine one part, water four parts, which he allows to remain in from one to four hours. As the membrane becomes accustomed to the glycerine he rapidly increases the proportion of it in the solution until he uses equal parts of it and water. He advises plugging the anterior nares with absorbent cotton, which prevents the tampon from being expelled. He has been experimenting with this treatment for the past six months, and thinks it is of great benefit in reducing many cases of hypertrophies.

Dr. A. De Vilbiss, of Toledo, contributed an interesting paper, entitled

SURGICAL TREATMENT IN DISEASES OF THE NOSE,

in which he said until recently few diseases have caused more dissatisfaction in their treatment than chronic nasal catarrh. He did not wish to be understood that in every case of nasal catarrh there is a demand for surgical interference, but in every case that demands operation a catarrhal condition of the nasal passages was usually found to exist. He had given relief from frontal headaches, mental depression, etc., by the removal of hypertrophic tissue from the middle turbinate. He believed the time was not far distant when the sphenoidal sinus, frontal sinus, post and anterior ethmoidal cells (after death) would be looked into and examined to find a special cause for certain symptoms that existed during life and the answer found. Schwable, Axel, Key, and Retzius have demonstrated the fact that not only can the lymphatics of the nasal mucous membrane be injected from the subdural and subarachnoidal spaces, but if force be used the fluid will pass through the lymphatic canals to the surface of the nasal mucous membrane. Permanent nasal stenosis should be relieved by an operation, as it is due to either traumatism, hypertrophic tissue over turbinate bones, thickening of tissue or deflections of nasal septum, gelatinous polypi, adenoma of vault of pharynx, fibromata or sarcomatous tumors, and the only source of relief is their removal or correction of misplaced parts. Preparatory to operating he always cleanses the nasal cavities of acrid matter and protects the cut surfaces after operation by keeping them covered with iodized or carbolized albolene or vaseline. Hemorrhage, if necessity demands it, he controls by cotton plugs. If the source of hemorrhage is well back in the nasal cavities he uses small cotton plugs tied with a string in the form of a kite-tail, which are easy to introduce and easy to remove.

## Friday, October 11th—Third Day.

At the solicitation of Dr. Seth S. Bishop, of Chicago, a committee was appointed by the President to co-operate with the United States Hay Fever Association, with reference to the investigation and treatment of hay fever, to report annually.

Dr. R. S. Knode, of Omaha, contributed a paper on the

IMPORTANCE OF CONSTITUTIONAL TREATMENT IN RHINO-PHARYNGEAL INFLAMMATION,

in which he said the rhinologist ofttimes becomes discouraged with all the means at his command when he finds that patients do not improve as he would like them to do; but if the history is carefully looked into there would be found some diathetical condition at the bottom of the nasal trouble, which, if the rhinologist could relieve, would cause a subsidence of the local inflammation. This catarrhal condition frequently extends into the stomach and intestines, and from the duodenum to the ductus choledochus, in which we have the combined symptoms of gastro-intestinal catarrh, associated with jaundice, and when the nutritive system becomes implicated there is a wide range of sympathetic disturbances which invariably follow.

The principal sympathetic phenomena transmitted from this condition is sick headache, depression, melancholy, sleeplessness, hypochondria; the heart's action is often disturbed; there is sympathizing dyspnœa, and to these may be added languor, lassitude, and irritable temper.

The general principles in the treatment of such cases would be a properly restricted diet, consisting of milk, stale bread, soft-boiled eggs, and well-cooked rice. If milk is not well tolerated, it should be peptonized; foods containing little starch and largely diluted with water are the best tolerated. Among the internal agents may be mentioned the alkaline carbonates, combined with purgative salines, especially where the nasal trouble is associated with disease of the stomach, which is a frequent complication in malarial districts; and in these regions no treatment is effective until we diminish the engorgements of the liver and spleen, and nothing accomplishes this so well as the use of alkaline and saline laxatives, and these may be assisted by small doses of mercurials. Carlsbad and other mineral waters have been extolled, but phosphate of soda and rochelle salts, if perseveringly used, may take their place. General hygienic treatment in all cases must be insisted on.

Dr. E. L. Siver, of Fort Wayne, Ind., read a paper, entitled

REFLEX INFLAMMATION OF THE NOSE AND THROAT.

The author reported a case of laryngitis, with aphonia, which lasted two weeks, and which, he thinks, arose from a deflected septum and posterior hypertrophy of the inferior turbinated bone.

Dr. A. G. Hobbs, of Atlanta, read a paper on

CATARRHAL NEURALGIA,

by which he meant to include not only the headaches and browaches that are caused by the pressure from nasal hypertrophies or foreign bodies, but all reflex pains that have for their origin pressure in the nasal cavities, whether they be located in the forehead, the temples, across the bridge of the nose, or over the cheek-bones. That such reflex pains do occur, and have for their cause pressure in the nasal cavities, was known long ago. If they were only occasional, or of short duration, they might not demand so much attention, but in many cases the pains are more persistent than the neuralgias from any other cause, and they, many times, produce a more profound impression upon the general system, indicated by a sense of lassitude, a haggard expression, a malassimilation, and a decided loss of weight. He had no statistics bearing upon the comparative frequency of catarrhal and ocular neuralgias other than his own note-book of the last three years. In it he found fifty-four cases under the combined headings: *Catarrhal neuralgia, ocular headache, and catarrhal and ocular neuralgia* combined; thirty-six cases occur under the first caption, fourteen cases under the second, and four cases under the third.

After recognizing the etiology of a case exhibiting these reflex pains, on account of the severity of the pain, tem-

porary relief should be given the patient by the application of cocaine sprays, or, in the case of complete stenosis, the cotton probe saturated with cocaine first, then the sprays. The effect should then be to reduce the pressure permanently by the means that is most rapid.

If the pressure be due to a polypus, extract it; if to a deflected septum, remove the deflection, and if it be (as is most likely the case) due to an hypertrophy, reduce it with the galvano-cautery, the snare, glacial acetic acid, or chromic acid. He most frequently resorts to the latter. After the removal of the pressure, pain ceases to a great extent, if not entirely; then the more soothing treatment of vaseline sprays, in combination with cocaine, pinus canadensis, oil of terebene, or oil of eucalyptus, daily or tri-weekly, will complete the resolution.

He knew of no class of cases that apply to the rhinologist for relief in which treatment gives more prompt and satisfactory results. Indeed, when there is no mistake made in the etiology the result is absolutely sure, if means are resorted to that are effectual in removing the pressure upon the terminal sensitive nerves that are distributed to the nasal mucous membrane.

Dr. Ely McClellan, of Chicago, read a paper on the "Physiological and Therapeutic Action of Certain Drugs in the Treatment of Affections of the Upper Air-passages."

THE ELECTION OF OFFICERS

resulted in the choice of the following:

*President*—Dr. A. G. Hobbs, Atlanta, Ga.; *First Vice-President*—Dr. A. B. Thrasher, Cincinnati, O.; *Second Vice-President*—Dr. E. R. Lewis, Indianapolis, Ind.; *Secretary and Treasurer*—Dr. R. S. Knode, Omaha, Neb.; *Librarian*—Dr. John North, Toledo, O.; *Member of Council*—Dr. C. H. Von Klein, Dayton, O.

Next place of meeting, Louisville, Ky., 1890, in conjunction with the Mississippi Valley Medical Association.

## NATIONAL ACADEMY OF SCIENCES.

*Regular Meeting, held at Philadelphia, Pa., November 12 to 14, 1889.*

SEVERAL of the papers read at this meeting were of great interest to the medical profession.

PROFESSOR WOLCOTT GIBBS and DR. H. A. HARE presented a further report on the results of the

SYSTEMATIC STUDY OF THE ACTION OF DEFINITELY RELATED CHEMICAL COMPOUNDS UPON ANIMALS.

These experiments are made with phenols of various composition. Their former report treated of ortho-, meta-, and pora-phenol; the present one of di-nitryl and tri-nitryl phenol. The effect of these substances on the heart and vagus nerve was carefully noted and described. One remarkable effect is the length of time between heart-beats, amounting in some cases to ten or even fifteen minutes, the animal being apparently dead, but kept alive by artificial respiration. These compounds kill quicker than the series previously reported on, and are more deadly in proportion to the amount of nitrogen contained. The position of $NO_2$ in the compound appears to determine the physiological effect of it. If this is so, it should give a clew to the physiological effect of drugs, and tend to place therapeutics on a scientific, instead of the present largely empirical, basis.

PROFESSOR WILLIAM H. BREWER, of Yale, read a paper on

HEREDITY OF ACQUIRED CHARACTERS.

He combats the view of Weissmann, who has published a volume in support of the proposition that characteristics acquired by individuals are not transmissible. Weissmann supports this proposition by experiments on mice, whose tails he cut off for successive generations, without inducing a tailless diathesis in their offspring. Brewer discussed four kinds of variation: 1, variation in size; 2, variation caused by exercise, training, and education; 3, variations due to disease; 4, characters assumed as the result of accident or mutilation. It is well settled that abundance of food affects the development and size of the individual, and of the offspring. All cattle-breeding proceeds on this postulate. A good example of the second class of variations is afforded by the evolution of the trotting horse, which began during the present century, and has proceeded so far as to produce a breed of horses which have actually lost the instinct to run, and trot even while they are young. Variations due to disease are equally powerful, but less susceptible of demonstration. An example is ringbone in horses, caused by accident to the individual, but transmitted to offspring. As regards heredity of mutilations, numerous instances are cited, among which were enumerated several cases of malformed fingers in offspring of parents whose fingers had been injured by accident. Conspicuous instances of sports developing into varieties are certain forms of merino sheep, and sequoia-trees of a certain type of foliage.

PROFESSOR BROOKS, in discussing the paper, opposed Brewer's view, and said that adaptations of nature have been evolved for the good of the species, not for that of the individual; hence they are not ordinarily transmitted, and the inherited effect of the influence of environment bears no appreciable effect on the evolution of species. Thus the larva of worker and drone bees is protected by an envelope of silk all around, while that of the queen bee leaves the abdomen unprotected, for the obvious purpose of enabling the mature queen to sting her larval rival when the swarming season is over, thus sacrificing the individual for the good of the community. The generation of polymorphic hydroids is an instance where the functions of generation are not exercised by the working members of the group, so that instincts acquired by experience are not transmitted.

The bodies of all animals are similar polymorphic aggregations of cells. The cells of the body which are exposed to external influences and vicissitudes are outside the line of succession in generation.

DR. H. C. WOOD, of Philadelphia, also opposed Brewer's conclusions. He

DOUBTS WHETHER THERE IS SUCH A THING AS HEREDITARY DISEASE.

It is not the disease, but the liability to disease that is inherited; in other words, the lack of power of resistance to external irritation. Consumption, for instance, is caused by the presence of an organism, the bacillus. This bacillus is certainly not inherited. We all breathe it, but not all become consumptive. Persons who have not sufficient power of resistance are affected by disease. These persons have inherited a weak constitution, or their powers of resistance have been weakened. This is all the heredity there is about it.

Dr. Wood also read a paper on

HYPNOTIC CASES WITHOUT SUGGESTION.

Hypnotism, he says, has long been used as a remedy by quacks and pretenders. After putting a patient in a hypnotic state, they make suggestions to him as to his physical condition, and on awaking from that state his condition is found to have improved in accordance with the suggestions offered. Thus we appear to have an alteration in nutrition without emotion, which is much more difficult to understand than alteration due to emotion. Nervous shocks affect the nutritive system, as numerous examples show. It seems more rational to suppose that the effect of hypnotism is due to the emotions felt while going into the hypnotic state than to suggestions made to the patient while in such state. There is nothing more uncanny than a room full of people in various stages of hypnotism, engaged in preposterous feats at the suggestion of the operator. The effect of such a sight was powerful even on the speaker (Wood). How much more so then on the uneducated.

This theory was tested on two patients, one of whom was paraplegic and the other affected with paralysis agitans. He hypnotized these, but made no suggestion to them, *i.e.*, said nothing about curing them, or that they would experience such and such sensations as the result of treatment, as mesmerists usually do. The first patient was cured by two applications of the treatment, the second by seven or eight.

Hypnotism is not efficacious in nerve diseases where the nerve-tissue has undergone changes that may be detected by the microscope. It is applicable to cases of hysteria, using the term in a broad sense, to include a large class of nervous diseases, such, for instance, as St. Vitus' dance and many others.

In this country, he can only hypnotize about half his patients; in France and Germany, nearly all.

## Correspondence.

### OUR LONDON LETTER.

(From our Special Correspondent.)

CHOLECYSTOTOMY—GLYCOSURIA AND ITS ASSOCIATIONS—PROPOSAL FOR FURTHER DRAINAGE LEGISLATION—THE ROYAL COMMISSION ON VACCINATION—NEW ANTISEPTIC METHODS.

LONDON, November 2, 1889.

THE first meeting of the Clinical Society for the winter session was held last week. The evening was occupied in discussing the subject of cholecystotomy. Mr. Mayo Robson, of Leeds, read a paper in which he gave an account of fourteen cases in which he had performed the operation. Eleven were cases of gall-stones, one was a case of empyema of the gall-bladder, and in the other two cases the operation was performed to relieve distention of the gall-bladder; the distention was found to be due to cancer of the head of the pancreas in one case, and in the other to cancer of the bile-duct. All the patients operated on for gall-stones recovered. Recovery also ultimately ensued in the patient operated on for empyema of the gall-bladder, though when operated on she was apparently dying from acute peritonitis; a biliary fistula remained for some time after the operation, but this was closed by cholecystenterostomy. The case of cancer of the pancreas terminated fatally on the eighth day from hemorrhage; the latter was due to a constant oozing of blood from the interior of the gall-badder and from the suture-punctures. In the case of cancer of the bile-duct, though there was intense jaundice there was no subsequent bleeding or other complication; of the cases operated on for gall-stones, six patients had sought advice in consequence of the presence of a tumor combined with other symptoms; five cases were operated on solely on account of symptoms, no tumor being detectable. In the former cases the operation was usually simpler, though in one case, where an apparently solid tumor was exposed which was due to the matting of the viscera surrounding the gall-bladder, so that the mass appeared at first to be a malignant growth, it was found impossible to shut off the general peritoneal cavity by suturing the parietal peritoneum to the gall-bladder, as the latter was practically destroyed by suppuration; drainage, with sponge-packing, was resorted to, to prevent general peritoneal infection. Mr. Robson remarked that operations performed on the strength of symptoms alone (no tumor being present) were not always easy, as the gall-bladder was often very small and could only with difficulty be brought to the surface. In one of his cases it was shrunk to the size of the last joint of the thumb, and was lying very deeply under cover of the liver, so that when he had incised it and removed several gall-stones from the duct, the lower part of the opening could not be made to reach the parietal peritoneum, and a piece of omentum was brought up and sutured on the one hand to the gall-bladder, and on the other to the parietal peritoneum, thus shutting out the general peritoneal cavity. Mr. Robson said he thought that omentum-grafting would often be found useful in abdominal surgery. It was first proposed by Dr. Sena for enterorrhaphy, but had not, he thought, been hitherto performed to overcome a difficulty of the kind he had met with.

Dr. Churton said he had undertaken a number of observations, in the post-mortem room and elsewhere, and had noticed that in most cases where the gall-bladder was small and closely packed with gall-stones, these could be reached by a needle through the liver. He had noticed that it was rare for a gall-bladder containing much mucus to have more than one stone in it. The thickening sometimes present in the neighborhood of the gall-bladder often looked much like cancer, and he had seen more than one operation abandoned on that account. Mr. Knowsley Thornton remarked on the difficulty of distinguishing between a distended gall-bladder and a tumor of the kidney. The most difficult cases were those in which there was thickening or suppuration around the gall-bladder. In one case he had cut through an inch and a half of thickened tissue, wondering all the time whether it was malignant. It was wonderful how rapidly this thickening cleared up after operation. The proposal to make the bile-duct open into the intestine he regarded as monstrous, and not one to be resorted to under any circumstances. Mr. Barker referred to a case in which he had operated for "impacted gall-stones" (diagnosed by two well-known physicians) and found nothing abnormal beyond a slight adhesion to the liver; the patient, however, had no more symptoms after the operation. Mr. Black alluded to a case in which there was jaundice, and which had been diagnosed as gall-stones, which turned out to be lead-poisoning. Several other gentlemen also took part in the discussion.

At the Medical Society of London, on Monday evening last, a discussion took place on diabetes and glycosuria, led off by a paper by Dr. Ord on "Some Obscure Points in Connection with Glycosuria." Dr. Ord laid special stress on gout, nervous strain and irritability, and bad habits of life—particularly chronic alcoholic indulgence—in the etiology of glycosuria. He also claimed that there existed some distinct corelationship between obesity and glycosuria, and between cardiac valvular disease and the same disorder. Some cases of glycosuria, occurring in association with Raynaud's disease, were mentioned. In all his cases of glycosuria, plus syphilis, he had been enabled to detect signs of hepatic disorder, but he was unable to formulate any definite conclusions therefrom, and he deprecated concentrating the attention upon the liver in considering the nature of glycosuria. Several cases of glycosuria in association with angina pectoris were referred to.

Dr. Pavy questioned the existence of any connection between obesity and glycosuria, but agreed that glycosuria was often associated with an enlarged or contracted (granular) kidney; the influence of the latter, however, was rather to diminish the amount of sugar in the urine. There was an analogy between the gangrene of diabetes and Raynaud's disease, and he mentioned cases in which glycosuria was associated with exophthalmic goitre. He declined to locate the seat of diabetes in the liver. Dr. Ralfe also thought we should look beyond malassimilation by the liver. The association of the disease with angina pectoris might be accounted for by diabetes leading to arterial and cardiac changes ending in degeneration. Dr. Savage observed that while both diabetes and insanity were directly hereditary, and it was common in insane persons to get a history of diabetes in the parents, yet it was rare to meet with glycosuria in cases of insanity (except puerperal insanity). Dr. Samuel West thought granular kidney rarely coexisted with diabetes. Sir William Roberts said that the variety of diseases with which glycosuria had been shown to be associated proved that they were still far from having grasped the essential

nature of the disorder. Dr. Mitchell Bruce suggested that some cases of diabetes were due to peripheral neuritis. Dr. Maguire thought that though gout might be the connecting link between some cases of granular kidney and glycosuria, yet there was a connection between diabetes and a certain degree of granular kidney in which no gouty element was present. When albuminuria occurred in diabetes it indicated a hardening of the kidney, and did not suggest a bad prognosis; it was, on the contrary, likely that the condition of the patient would improve.

The newly constituted governing body for London (The London County Council) has decided to apply to Parliament for powers to be given to the metropolitan vestries and district boards to enable them to inspect the drains beneath houses and to execute such works as may be necessary.

It is estimated that the inquiry being carried on by the Royal Commission on Vaccination will last about two years. It is to be hoped that the results may repay such an expenditure of time and labor.

New antiseptics seem ever to the fore. Sir Joseph Lister is to deliver an address at the Medical Society, on Monday next, on "A New Antiseptic Dressing." As new antiseptic methods seem so constantly needed, one cannot help making the reflection that the old ones cannot be wholly satisfactory. But perhaps this is unjust.

## OUR PARIS LETTER.

(From our Special Correspondent.)

IMMUNITY FROM MICROBIC INFECTION—DIABETES AS INFLUENCED BY THE CONDITION OF THE PANCREAS—THE MOVEMENTS OF THE TRACHEA—FATAL ACUTE HYDRARGYRISM—THE CAUSES AND PROPHYLAXY OF TUBERCULOSIS—THE TRANSMISSION OF SYPHILIS THROUGH SURGICAL INSTRUMENTS—INJURIOUS EFFECTS OF MILK DIET IN DIABETES.

PARIS, November 8, 1889.

AT the last meeting of the Academy of Sciences, Professor Bouchard read a memoir on the influence and the mechanism of the local lesion. His researches were made in conjunction with Dr. Charrin. The experiments undertaken established that among refractory animals, many of them destroy the microbes and thus create a localized inflammation. Dr. Bouchard then analyzed a work by Drs. Charrin and Roger, relative to the influence of the serum on the development of microbes. These experimenters show that, in the serum of diseased or vaccinated animals, the pathogenic microbes are developed less easily than in the serum of healthy animals. Not only are the microbes affected in their function of reproduction, but their functions of secretion are notably diminished, and are sometimes even suppressed, in the liquids of diseased or vaccinated animals. Even the form is altered. It results from this work that immunity partly consists in chemical modifications.

At the same meeting a work by Dr. Dujardin-Beaumetz, entitled "Pancreas and Diabetes," was submitted. This memoir was published some time ago, but the author wished to submit it to the Academy because it contained considerations which have been recently confirmed by authors in other countries. Dr. Dujardin-Beaumetz had already maintained several years ago that glycosuria resulted from the total or partial suppression of the pancreas.

Dr. Nicaise recently published a note on the movements of the trachea, which he studied by graphic tracings. He observes that formerly it was thought that there were constriction and shortening during expiration, and, inversely, dilatation during inspiration; but, according to the author, it is just the contrary which is the case.

Dr. Legrand publishes, in the *Annales de Gynécologie*, a case of fatal acute hydrargyrism, resulting from two intra-uterine injections of a 1 per 2,000 solution of corrosive sublimate. The author states that this case may be added to a certain number of others recently published, and showing that the employment of these injections after parturition may frequently be followed by death. In the case under notice, only two injections were practised, at an interval of three hours, with ten litres of the mercurial solution as above indicated, the recipient being placed about one metre above the level of the bed. This injection was followed by one of boric acid. The next day, the first phenomena of intoxication manifested themselves, and death took place three days later. The autopsy showed the existence of characteristic lesions in the intestines. Dr. Legrand believes that in this case the intoxication was produced by the penetration of the sublimate direct into the circulation. The retention of the placenta in a little-developed uterus probably favored the gaping of the uterine sinuses. A slight pressure caused in a very short time the penetration of the fatal dose of the poison. The practical conclusion is, that the corrosive sublimate, even in weak solution, should be employed for intra-uterine injections with great circumspection. Its use is dangerous, particularly when there is retention of the placenta in the uterus incompletely developed, as in cases of abortion. In any case, it is prudent to make only feeble pressure, exactly determined, and never surpassing a column thirty centimetres high. Finally, the free escape of the liquid should be attended to with great care.

In the debate that has been going on at the Academy of Medicine on the causes and prophylaxy of tuberculosis, Dr. Lancereaux spoke of the influence of alcohol on this affection. He stated that the effect of alcohol on the organism, in retarding metabolic changes and checking combustion, diminishes the appetite, and renders the tissues an easy prey to the attack of the tubercle bacillus. Tuberculosis in alcoholic subjects always presents about the same features. It usually begins on the right apex behind, though this localization is not altogether special to this form of disease. Hæmoptysis is often an early symptom, and tends to recur. In certain cases it is the first symptom to be met with in persons of apparently robust health, indicating the advent of the disease which is shortly to carry them off. The course of the disease is often very rapid, though intermissions are occasionally met with.

Some time ago Dr. Lancereaux brought to the notice of the Academy the possibility of the transmission of syphilis through surgical instruments. This he has just demonstrated by a note on two cases, which he read at the meeting of the Academy this week. In the first case, the patient had been inoculated by an aurist who had several times practised catheterization of the Eustachian tube. Dr. Lancereaux observed that this was not the first time that such an accident occurred, and that it will not be the last if the specialists do not take the trouble to minutely disinfect their instruments. In the second case it was a lady, who was infected by a dentist who had practised on her a certain number of operations for the fixing of artificial teeth. Dr. Lancereaux here remarks that not only dentists, but also hair-dressers and barbers, should disinfect their instruments, and the employment of a disinfecting solution should be ordained by law. In fact, the same may be applied to all surgeons, as among them some are not scrupulously particular in this respect.

In a note on the injurious effects of the milk-diet in diabetes, Dr. Mascarel relates the case of a patient, a man aged forty-eight, who for a year past had been suffering from rheumatism and herpes, associated with an intolerable thirst, to assuage which he had been advised to drink large quantities of raw milk (four or five litres in the twenty-four hours). He was emaciated and the tongue was coated. He complained of anorexia, constipation, and a dry, hot skin. The pulse was small, 100. The secretion of urine was excessive, and the urine itself was clear and free from albumin. A few days later he was found dead in bed. At about the same date a young man of twenty-seven was in the habit of drinking from four to six litres of milk daily to assuage his thirst. This

patient had been examined and found to be suffering from diabetes. After three weeks of the exclusive and excessive use of milk he died suddenly with cerebral symptoms. Dr. Mascarel concludes that the only circumstance in which diabetics should be ordered milk is when the urine is found to contain albumin as well as sugar.

## THE JOHNS HOPKINS HOSPITAL AND THE DISPENSARY ABUSE IN BALTIMORE.

To the Editor of The Medical Record.

SIR: Your notice on page 487 of THE RECORD is not unsurprising, and the great "Johns Hopkins Hospital" is possibly *not* an "unmixed blessing" to our profession; but the members thereof have themselves alone to blame in the matter. *Tempora mutantur, et nos mutamur in illis*—Massaria, who "preferred to err with Galen rather than be in the right with someone else," has indeed passed away; but abject devotion to authority still shows itself in our own as well as in other callings—simply as the result of habit rather than reflection. The "Johns Hopkins" was long in process of incubation, and each step in its progress, from the embryo to the fully developed mastodon, was duly noted, discussed, and examined, and finally earnestly indorsed and recommended by the regular profession as the *summum bonum* of everything that might conduce to the best practical application of *that art* to which all appeal for health, strength, and life. These are unquestionable facts; and there should therefore be no complaint when the new-comer, duly and truly prepared, having all the testimonials of merit that name and fame can give, goes right to work, like a regular South Sea Islander, and deliberately eats up and devours his own progeny and progenitors, without the slightest compunction—and finds plenty of food.

Respectfully yours,
B. F. GROVE, M.D.

209 East Preston Street, Baltimore, Md.,
November 4, 1889.

## Army News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 10 to November 16, 1889.*

MACAULEY, C. N. B., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect about the 29th instant. Par. 2, S. O. 166, Department of the Missouri, Fort Leavenworth, Kan., November 8, 1889.

MAUS, LOUIS M., Captain and Assistant Surgeon. By direction of the Secretary of War, having relinquished the leave of absence on surgeon's certificate of disability, granted him in S. O. 249, October 25, 1889, from this office, will, upon being relieved from duty at Fort Porter, N. Y., as directed in S. O. 242, October 17, 1889, from this office, proceed without delay to Fort Stanton, N. M., and report in person to the commanding officer, Department of Arizona. Par. 8, S. O. 261, Headquarters of the Army, A. G. O., Washington, November 8, 1889.

CRAMPTON, L. W., Captain and Assistant Surgeon. From Fort Lyon, Col., to Fort Sheridan, Ill. Par. 3, S. O. 167, Headquarters Department of the Missouri, Fort Leavenworth, Kan., November 9, 1889.

CORBUSIER, W. H., Captain and Assistant Surgeon. From Fort Hays, Kan., to Fort Lewis, Col. Par. 3, S. O. 167, Headquarters Department of the Missouri, Fort Leavenworth, Kan., November 9, 1889.

IRES, F. J., First Lieutenant and Assistant Surgeon. From Fort Lyon, Col., to Fort Sill, Ind. Terr. Par. 3, S. O. 167, Headquarters Department of the Missouri, Fort Leavenworth, Kan., November 9, 1889.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 16, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 33 | 11 |
| Scarlet fever | 34 | 2 |
| Cerebro-spinal meningitis | 2 | 1 |
| Measles | 34 | 3 |
| Diphtheria | 76 | 16 |
| Small-pox | 0 | 0 |
| Yellow fever | 0 | 0 |
| Cholera | 0 | 0 |

THE PATHOLOGY OF HEART-FAILURE.—In a paper read before the British Medical Association on the subject of cardiac failure, Dr. Mott insisted that the whole circulatory system must be taken into account in considering this important subject, not only in the cardio-vascular system, but in the contained blood also. In all cases of failure of the circulation there was some alteration in the nutrition of the cardio-vascular system. The heart itself, which acted as the force-pump, was in every case disorganized. In myocarditis, fatty degeneration, and some other conditions there was usually coronary obstruction. This was very important, as in forty-nine out of fifty cases examined there was organic disease of the myocardium. It was necessary to examine the coronary arteries, not only at their openings into the coronary sinuses, but also for some distance from the mouth, as it was frequently found that there was constriction at as much as one inch from this point. In partial obstruction the degeneration was not usually fatty, but was often merely a part of a widespread degenerative process associated with chronic inflammation, affecting the cardio-vascular system, especially the heart and kidneys. In these cases the termination was not sudden, and was quite different from those cases in which there was sudden failure from imperfect filling of the cerebral and coronary vessels, as when the patient sat up suddenly. In most of the cases of complete obstruction of a principal branch of one of the main trunks, with partial occlusion of the other, there had been a syphilitic history. Of five such cases four had died suddenly from syncope due to fatty degeneration of the myocardium. Dr. Mott then discussed the conditions met with in chronic alcoholism, in which there was no affection of the coronary arteries, but in which fatty degeneration had been followed by sudden and fatal syncope. In cases of fatty degeneration he pointed out how the arrangement of the muscles led to imperfect action of the valves—the musculi papillares, in which the process is best seen, being the continuation of the figure-of-eight bundles of muscular fibres in the walls of the cavities of the heart. This explanation might be readily adapted to Mr. Williams' theory of "delirium cordis." In no case was it sufficient to make a diagnosis without the aid of the microscope, and he recommended that osmic acid or Pal's modification of Wright's method should always be used in order to determine the amount and distribution of fatty degeneretion in the myocardium. Fatty degeneration alone did not produce angina pectoris, as was evidenced from those cases of pernicious anæmia in which the fatty degeneration was well marked, but where there was no angina at any stage of the disease. A description of acute and chronic myocarditis was given, and it was pointed out that the former was invariably associated with acute fatal pericarditis.—*The Lancet.*

SENILE CHANGES IN THE BONES.—In the *Illustrated Medical News*, March, 1889, Professor Humphry contributes an article on the changes in the bones in old age, and illustrates his remarks with some valuable illustrations. To the naked eye these changes consist in an ab-

sorption of the cancellous structure, commencing in the parts which are most cancellous, that is, where the bony plates are thinnest, where the marrow is most abundant and most vascular, where the leucocytic and other agents in absorption are most abundant, where, accordingly, we might expect the processes of absorption to be most ready to take advantage of any failure in the nutritive and resisting qualities of the bony tissue. In the early condition the several parts of the skeleton are solid; as they become hardened and added to at the exterior they become hollowed out in the interior into cancellous spaces, medullary canals, and air-containing cavities; this change continues through life in gradually diminishing degree; and, as old age advances, the subtraction from the interior exceeds the addition to the exterior, and the bones gradually decrease in weight and strength. The muscles at the same time become weaker, so that it is almost as rare to have a spontaneous fracture of a bone from muscular action in old age as it is in youth or middle age. The author shows by diagrams how in old people the head of the femur becomes thinned and liable to fracture. This predisposition to absorption in the cancellous parts is met with in the ends of the long bones in all aged people, which causes their liability to fracture. The tendency to absorption of the cancellous parts of the skeleton is also seen in the alveolar processes of the jaws, whereby the teeth are loosened and often drop out. In the body of the lower jaw these changes are very marked; the thin lower bar alone remains with the mental foramen upon or near the upper edge; in the upper jaw alveolar processes become, in course of time, completely cleared away; the level of the palate is continued to the margin of the bone, the whole maxilla (the walls of the antrum more especially) becomes very thin, and the nasal spine and the cheek-bones are left outstanding in relatively strong relief. An exception to the progressive cancellous absorption and diminution of weight in the bones of old people is not infrequently to be found in the skull, more particularly in the calvarium. This part in some cases becomes very thin and light, in others it becomes thicker from deposit on the interior, consequent, probably, on the lessening of pressure upon it associated with the brain-shrinkage of age; in some of these latter cases it is very porous, the diploe being increased; in others, however, it is dense and heavy, as well as thick, the diploe being encroached upon and perhaps obliterated. The contrast in some cases presented by the thick heavy calvarium, and the thin light facial bones, is very striking, the skull of many old people weighing many ounces over the average; and this is due to increased thickness and density of the bones enclosing the cranial cavity. This senile thickening and "senile sclerosis" differ from the changes in osteitis deformans, inasmuch as they affect the interior of the skull and the diploe rather than the exterior. So far as the author knows, the cranial wall is the only part of the skeleton in which this process occurs. The increased density and weight of the skull when the rest of the skeleton is becoming less fitted to bear weight is a strange and not easily intelligible anomaly.—*Medical Recorder.*

Incompatibility of Antipyrine and Chloral.—M. Blainville, a pharmacist of Paris, was called upon to put up a prescription containing four grammes of antipyrine and five of chloral hydrate in fifteen grammes of water. An oily precipitate was immediately thrown down which resembled neither chloral nor antipyrine in taste, but recalled somewhat that of coriander-seed. A mixture of antipyrine and quinine is also incompatible, both substances being at once precipitated from the solution.

The Tri-state Medical Association, recently organized by the physicians of Georgia, Alabama, and Tennessee, held its first annual meeting in Chattanooga, Tenn., on October 16 and 17, 1889. The meeting was called to order by Dr. Wise, President of the Chattanooga Medical Society. After a prayer by the Rev. Dr. J. W. Bachman, the address of welcome was delivered by Dr. G. W. Drake. The following sessions were devoted to the reading and discussion of scientific papers. The election of officers resulted in the selection of the following: President, Dr. J. B. Cowan, of Tullahoma, Tenn.; First Vice-President, Dr. A. Boyd, of Scottsborough, Ala.; Second Vice-President, Dr. James B. Edge, of Demond, Ga.; Third Vice-President, Dr. Lelwellyn Barber, of Tracy City, Tenn.; Secretary, Dr. Frank Trester Smith, of Chattanooga, Tenn.; Treasurer, Dr. B. S. Wert, of Chattanooga. The next meeting of the Association will be held in Chattanooga on October 21, 1890.

Double Parotitis of Reflex Origin.—At a meeting of the St. Petersburg Naval Medical Society, Dr. Milonas communicated the following curious case. An exceedingly nervous and emaciated recruit, aged twenty-two, fell ill with a severe attack of right-sided croupous pneumonia. On the third day there supervened incontinence of urine, alternating with retention, while on the ninth there developed a prostatic abscess, determining a complete prolonged retention, and necessitating catheterization. The latter proved to be extremely difficult, since, on one hand, any attempt at introducing the instrument into the urethra gave rise to general clonic convulsions, while, on the other, the end of the catheter deviated from the urethra into the prostatic abscess. Several hours after those repeated and prolonged manipulations there suddenly appeared rigor and pain about the right temporal region, which were swiftly followed by intense swelling of the corresponding parotid, rapidly passing into suppuration. The patient's micturition being at the time restored, no catheter was used for the next six days. On the seventh, however, another prolonged attack of retention of urine took place, and catheterization was again resorted to. It was most rapidly followed by the development of a left-sided suppurative parotitis. The patient ultimately recovered, though but very slowly. Analyzing his case, Dr. Milonas comes to the conclusion that on either occasion parotitis was caused in a reflex way by the said intense irritation of the patient's genito-urinary tract. During a discussion Dr. Balinsky adduced three similar instances of reflex parotitis from his own practice, all referring to women. In one of the patients, who had undergone some operation for vesico-vaginal fistula in the morning, the subsequent insertion of a catheter *à demeure* was followed at nightfall by swelling of one of her parotids. In another, suffering from uterine flexion, the introduction of a sound into the womb gave rise on each occasion to a rapid painful enlargement of the gland. In the third, parotitis developed shortly after the amputation of the womb, preceded by the introduction of a catheter into the bladder.—*The Journal of Laryngology and Rhinology.*

A Second Sarah.—Under this caption the St. Louis *Post-Dispatch* of October 15th prints the following special from Fort Smith, Ark.: "Yesterday a woman living in the mountains here, named Sarah Gates, aged seventy-one, proved herself a second Sarah by giving birth to a well-formed and healthy male child. Two years ago Mrs. Gates, then a widow, married William Gates, a young hired hand on her farm. The case is exciting a good deal of interest among physicians." A correspondent from Little Rock suggests that this remarkable tale be investigated by some of the Fort Smith physicians, who are said to be interested in the occurrence. We should be glad to hear from anyone who has any knowledge of the actual facts in the case.

Gonorrhœa in a Boy Five Years of Age.—Dr. Custer, of Manayunk, Pa., reports in the *Medical and Surgical Reporter* of October 19, 1889, the case of a boy, aged five, who was brought to him for treatment on account of an aggravated case of gonorrhœa. The boy was remarkably well developed for his age, and investigation showed that he had been sleeping with a young woman who was suffering from leucorrhœa.

## Original Lectures.

### ON VITAL AND MEDICAL STATISTICS.[1]

BY JOHN S. BILLINGS, M.D.,

UNITED STATES ARMY.

#### LECTURE. I.

I PROPOSE in these lectures to speak of vital and medical statistics, and of some of their relations to each other and to scientific and practical medicine and sanitation. The discussion will include such points as, character of the data required; methods of obtaining them by the census, by registration, and in other ways; relations of physicians to this kind of work; methods of compilation and forms of publication; the best existing sources of such data; and some of the more common fallacies in drawing conclusions from the data as ordinarily published.

These and other points will be considered in their practical application to certain questions which, I hope, may be of interest to you, both as citizens and as physicians—as, for example: Is the average longevity of man in civilized countries increasing? What data are required to practically judge of the relative healthfulness of different localities, or of the same locality at different times? What are the relations of certain forms of disease to race, to climate, to locality, to occupation? What is the relative tendency to increase of population in this country in the white and colored races? What is the statistical evidence with regard to improvement in practical therapeutics as arrived at from hospital data, from death-rates in obstetric practice, etc.?

Statistics, and discussions of statistical methods are, as a rule, dry and uninteresting subjects, and it is with very considerable doubt and hesitation that such a topic has been selected for these lectures. I have no new discoveries to announce, and those who are practically familiar with statistical research will find some of my statements rather elementary; but the subject is not one which lies within the ordinary range of medical studies, the data are widely scattered in literature, and I hope, at least, to be able to remind you of some of the numerous points which you may have once known, but which may have been forgotten owing to the pressure of other studies and duties.

Statistics are somewhat like old medical journals, or like revolvers in newly opened mining districts. Most men rarely use them, and find it troublesome to preserve them so as to have them easy of access; but when they do want them, they want them badly.

The use of statistics may be compared to that of the microscope or the spectroscope, as pointed out by Mr. Hooper.[2] He says:

"It is found convenient to speak of the science of Spectrum Analysis, and of Microscopical Science, because complicated scientific instruments require that their users should understand them and be able to adjust them, and the knowledge which enables the operator to use his instrument and put it in order is important enough to be termed scientific. In this sense it might be possible to speak of a Science of Statistics. The knowledge suitable for the purpose of practising the art of Spectrum Analysis covers a wide field, necessitating a study both of the instrument itself and the phenomena which it reveals; and the same may be said of the knowledge needed for successfully practising the art of statistical analysis, and in this sense this knowledge may be termed scientific"

If we choose to accept the definitions of French, German, and many English writers, the term will include a large part of sociology.

Circumstances have made it necessary for me to endeavor to ascertain the character and amount of the statistical data which have been published, and which are available for those who wish to make special studies of the relative frequency of certain diseases, deformities, or disabilities; of their causes and results, especially as to mortality; or of the relations which exist between disease and death, and such conditions as sex, age, race, soil, climate, occupation, etc.; and in the course of this investigation it has seemed to me that many physicians are not as familiar with statistical methods, and with existing sources of information relating to vital statistics, as it is desirable that they should be to enable them to judge properly the value of the arguments and conclusions presented by those who make use of such data, even though they themselves may have no desire or intention to use statistical methods of research.

There are many fallacies and errors connected with vital and medical statistics as ordinarily collected and used, and it is highly desirable that the physician should be aware of the more important of these, since he is constantly appealed to for decisions as to their true significance and value. "It is as easy to tell lies with figures as with words, and bigger ones;" but while we occasionally meet with deliberate falsifications of the records, made for the purpose of magnifying or diminishing the apparent mortality or prevalence of a particular disease in a given locality, or to maintain an anti-vaccination thesis, these are not so frequent as are the errors of involuntary misstatement and misinterpretation into which those not familiar with methods of collecting and tabulating statistics are so liable to fall. Those who are not familiar with the methods of obtaining and compiling statistics of this kind are apt to be either unduly credulous or unreasonably sceptical as to their real use and value—to use the first figures which come to hand, and thence derive conclusions which are not warranted, or to reject the plain teaching of carefully compiled statistics in favor of general assertions which have no firm foundation, but which are in accord with preconceived opinions. My experience with those seeking statistical data is that the majority begin by looking for those data which are in favor of some particular conclusion with which they commence, rather than by selecting data with reference to their probable completeness and accuracy, and accepting the conclusions which may be legitimately drawn from them, whatever they may be.

Those who are engaged in the collection and compilation of official mortality and vital statistics are often at first the most sceptical as to their accuracy and utility, for their attention is so frequently and forcibly drawn to errors in the individual data that they conclude that the whole mass is unreliable; and the difficulties in the way of obtaining complete and reliable figures are seen to be so great that they incline to give up the whole matter in de-

[1] The Cartwright Lectures, delivered before the Alumni Association of the College of Physicians of New York, November, 1889.

[2] The Method of Statistical Analysis. A paper read before the Statistical Society of London, by Wynnard Hooper, B.A., January 18, 1881. Statistical Society of London, Journal, vol. xliv., p. 31.

spair. Continued study of the subject, however, shows that many valuable conclusions or suggestions can be derived from imperfect data, and that in large masses of figures the errors either tend to neutralize each other, or to produce a constant effect in one direction which can be calculated and allowed for, so that those who have had the greatest experience are most convinced of their value. It is true that, in statistics, the inferences cannot be more accurate than the data on which they are founded, but we do not look for scientific exactness from them so much as for an estimate of probabilities.

The methods which we have for advancing our knowledge of the laws of human life, of the causes of abnormity, disease, and death in man, and of means of sanitation or therapeutics, may be grouped into two classes, viz., observation and experiment—which, however, are often combined.

In the experimental method we seek to make a direct test of the variation of one particular condition, or set of conditions, upon the living organism, all other conditions being kept uniform as far as possible. Some such experiments can be made on man, but the greatest number of the problems which we may hope to solve by this method, and among these the most important, can only be approached by experiments on the lower animals. Within the last twenty years experimental physiology and pathology have made great advances, and these methods, so far as they are applicable, give more definite results, and are more immediately satisfactory, than those derived from comparison of observations in which no definite experimental variations have been made; but so far as regards causes of disease, or the action of supposed methods of prevention, or of remedies, it is unfortunately the case that we cannot draw accurate conclusions as to what will happen in man from what is observed to happen in animals. In the first place, there are many forms of disease in man, and those among the most important, as regards the suffering and loss of productive power and of life which they produce, which cannot, with our present knowledge, be experimentally produced in animals, and which rarely or never occur in them.

For example: Yellow fever is a disease which, from analogy, we have reason to believe may be due to the action of one or more specific micro-organisms, or, perhaps, I should say, to the products of such organisms. We find a dozen different kinds of bacteria in persons suffering from yellow fever, and, by dint of much labor, these have been isolated and cultivated outside the human body. The problem is to determine positively, and with scientific precision, which, if any, of these is the true, essential cause of the disease. The mode of doing this is by producing the disease in a perfectly healthy person or animal by the inoculation of the suspected organism. But, thus far, we have failed to find any animal in which a disease, which can be considered as specifically identical with yellow fever, can be produced by any method; and I need hardly tell you that inoculations of such a disease as this in a human subject, under conditions which would make the results of such inoculation scientifically trustworthy, are impracticable and unjustifiable.

Those forms of disease which are common to animals and man, such, for instance, as anthrax, tuberculosis, tetanus, hydrophobia, the ordinary forms of suppuration, and, perhaps, also typhoid fever, are being pretty thoroughly worked out by means of such experimental inoculations as I have just referred to; and we are able to say, with a great degree of precision, not only that these diseases are due to specific forms of bacteria, but to determine enough of the characteristics of these forms to be able to identify them wherever they are found.

For the great majority of diseases, however, this experimental method of determining the causes, and therefore, necessarily, experimental methods of prevention and treatment, cannot be employed in such a way as to distinctly isolate the effect of the particular agent or circumstance which we are investigating, and we must therefore resort to the other mode of advance of knowledge which has been referred to, namely, that of observing the phenomena as they occur in man, and endeavoring to so group the results of these observations as to determine the influence of a particular condition or set of conditions while all other circumstances remain uniform.

This method of observation may, for our purposes, be again divided into two categories. The first is that which is used in individual cases, being the form applied by the physician to each case which he has to treat. It also includes the sort of investigation which may be made in a single household, a small community, or a thinly populated district, to determine the course and cause of a particular form of endemic or epidemic disease, where the conditions affecting each family or dwelling can be studied in detail somewhat as the detective of modern fiction follows his clews. By the combination and comparison of detailed studies of this kind the greater part of our present system of diagnosis, prognosis, and therapeutics have been evolved; but it has been and will be a slow process, for each man differs from every other man in structure and mode of function, and the conditions of the environment are so multiform, and so variable in space and time, that "experience is doubtful, and judgment difficult." We must therefore try to supplement the information thus obtained by that derived from the second kind of observation above referred to, namely, that of collecting a few data with regard to great numbers of people, especially where these are accumulated in thickly settled localities, forming what is called the statistical method as applied to different communities. By the first method we compare individual with individual, and do so with considerable minuteness of subdivision of the conditions studied; by the second method we compare the vital phenomena of communities with those of other communities, but only on broad lines and in relation to circumstances easily noted.

The object of vital statistics is to classify and arrange the facts relating to the quantity and character of human life under different circumstances, for the purpose of determining the effect upon it of each of these circumstances taken singly, or of two or more of them acting together. The results thus obtained form an important part of the scientific foundations of sociology, of political economy, and of preventive medicine. It deals with masses of men and not with individuals, and its conclusions are, for the most part, applicable only to large bodies of people; yet its data are derived from individual records, and its results are accepted in many cases as a sufficient guide for individual action. They do not, in this respect, differ essentially from most of the motives which actuate us in daily life. The farmer sows his seed, the manufacturer builds his mills, the physician writes his prescriptions, and you come to hear this lecture from motives of probability; not carefully formulated in most cases, or capable of expression by a formula, but, nevertheless, in accordance with the doctrine of chances as determined by previous experience.

The term "vital statistics," in the sense in which I use it in these lectures, corresponds almost precisely to the French term "démographie" or the German "demologie," being applied to the circumstances of human life only, in the sense of Korosi's definition that it is the science of the physical life of human society. We will first consider briefly the sources of information and the character of the original data available for this study; second, the methods of arranging and using these data; and, third, the value and applicability of some of the conclusions which may be drawn from them, especially in that branch known as medical statistics.

The essential data of vital statistics are derived from enumerations of the living population and from records of births, marriages, and deaths.

The numbering of the people is effected by a census, a term derived from the Roman Censors, a part of whose duty was to make such counts. Such enumerations

were made by Moses (1490 B.C.), David (1017 B.C.); in Greece, 650 B.C.; and in Rome, beginning 566 B.C. They were probably made also in Assyria, but the Accad records have not yet been found. In modern times the first country to make a count was Sweden, in 1749. The first census in the United States was taken in 1790, as a necessary means of carrying out the constitutional provision that the basis of representation for the several States should be the number of the population in each. The first census in England was taken in 1801, and showed the number of persons, with distinction of sex, the number of houses, the number of families, and a rough statement of occupations under the general classification of agriculture, trade, manufactures or handicraft, and all others.

The first satisfactory English census, giving distinction of age, sex, occupation and birthplace, the number of persons blind and deaf and dumb, was the census of 1851. This was the first census whose data could be used in connection with the general system of registration of births and deaths.

The first attempts to take a census in a country have usually excited more or less suspicion and opposition, from fear that the information obtained would be in some way used to oppress the people. For example, several attempts to take a census have been made in Hayti but have always given rise to insurrection, and have always been defeated, owing to the belief of the people that it would in some way lead to their losing their liberty.

In the first censuses the object was to determine the number liable for military service or qualified to vote, or to fix rates of taxation, and the records were very brief. In the first United States Census the only data called for on the schedules were, names of heads of families, free white males over sixteen, free white males under sixteen, free white females, all other free persons, slaves.

The record of age was first made in the English Census in 1821, was omitted in 1831, and resumed in 1841. As the census records came to be more and more relied upon as a basis for legislation, additional details were introduced, and the above table shows those now included in the censuses of some of the principal countries of the world.

The relative importance of each of these details in studies of vital statistics varies greatly according to the purpose to which they are to be applied; but to physicians, sanitarians, and those interested in life insurance, the dominating factors are age, sex, and race. The power of reproduction, the tendency to death, and the liability to certain forms of disease, vary greatly at different ages in the two sexes, and this gives rise to corresponding variations in the disease- and death-rates of populations of different localities, or of the same locality at different times, when these populations differ as to the relative proportion of young and old, or of male and female, which they contain. These variations we must ascertain if possible, and estimate the influence of, in order to make reliable and useful studies of the effects upon human life of climate, altitude, race, occupation, or other conditions of the environment. In the course of these lectures I shall often have occasion to refer to this dominating influence of age, and to point out errors due to neglect of this factor, which is by no means an easy one to determine for many places, at many times. Even the census data require corrections, since people do not give their ages accurately to the enumerators. The tendency is to answer in round numbers as, 20, 30, 40, etc., and to a less but still marked extent, as 25, 35, 45, etc.; but the effect of this can be done away with to a considerable extent by properly grouping the individual data, as I shall explain presently. Ages over 90 are largely overstated, and the ages of women between 25 and 50 are largely understated; but these errors, being comparatively constant, and influencing the data of all communities, do not lead to erroneous conclusions of importance in comparing different communities, if the distinction of sex be observed.

One of the most interesting fields of study in vital statistics is the relation of race and color to birth-rate, to certain forms of disease, or to the liability of death at certain ages.

This country is, as you know, the great mixing ground for different races of the human family, and, while the mixture is rapidly becoming so intricate as to make it impossible to distinguish the several strains, it is still true that there are in this country large groups of men of quite distinct races, the record of disease and death in which would form valuable material for study upon this point were it possible to collect them.

From the sociological and political point of view this is particularly the case with regard to the negro and to those having a mixture of negro blood; and in the Southern States such questions as the following are of great practical interest. Is the negro population increasing faster than the white? Is the proportion of mixed bloods, such as mulattoes, quadroons, etc., increasing in proportion to the general population? Are the fertility and expectation of life of mixed bloods greater or less than those of pure whites or pure blacks under the same circumstances of environment? We will return to these questions hereafter; at present I merely refer to them as being the probable reason for the introduction into the law for taking the next census of a special clause providing "that the population schedule shall include an inquiry as to the number of negroes, mulattoes, quadroons, and octoroons," an attempt to obtain information which has not heretofore been sought in this way. In obtaining the records of deaths occurring during the census year beginning June 1, 1889, an effort will be made to have the deaths of colored persons distinguished into those of pure negroes and those of mixed blood. It will probably be impossible to obtain the data for either living population or deaths with the minuteness of subdivision indicated by the words "mulatto," "quadroon," and "octoroon"; but there is reason to hope that in many sections of the country we shall be able to distinguish those of mixed blood from the pure blacks and the pure whites, and to give some opinion with regard to their diseases and death-rates. The results of the last census, although imperfect, show such marked differences as regards the mortality from certain diseases, not only between the whites and the blacks, but between those of English, Irish, and German descent, as to make it certain that it will be worth while to pursue this branch of inquiry more minutely as opportunity is offered to us hereafter. The following table, taken from the last census, indicates the difference in the proportion of deaths from certain causes to the deaths from all causes in the white and colored population in the South and in those of Irish and German parentage in the North.

| Deaths from— | White. | Colored. | Irish Parentage. | German Parentage. |
|---|---|---|---|---|
| Abortion | 0.9 | 1.4 | 0.5 | 0.8 |
| Accidents and injuries | 43.8 | 67.6 | 61.0 | 52.5 |
| Alcoholism | 2.5 | 0.7 | 6 7 | 2.7 |
| Cancer | 19.1 | 7.8 | 24.3 | 25.8 |
| Childbirth | 13.9 | 24.8 | 14.1 | 18.3 |
| Consumption | 126.2 | 139.1 | 198.4 | 123.6 |
| Croup | 26.1 | 21.8 | 15.1 | 23.2 |
| Diphtheria | 39.8 | 17.4 | 42.1 | 72.7 |
| Diseases of the bones and joints | 3.1 | 2.0 | 3.1 | 2.5 |
| Diseases of the digestive system | 46.8 | 49.6 | 43.8 | 47.1 |
| Diseases of the nervous system | 119.1 | 96.9 | 94.7 | 109 4 |
| Enteric fever | 33.9 | 31.7 | 17.4 | 29.6 |
| Heart disease and dropsy | 56.1 | 64.5 | 62.3 | 60.9 |
| Hooping-cough | 14.3 | 33.0 | 6.0 | 8.4 |
| Infanticide | 0.05 | 0.14 | ..... | 0.02 |
| Malarial fever | 30.7 | 48.3 | 12.9 | 14.1 |
| Measles | 9.1 | 17.7 | 5.3 | 8.5 |
| Peritonitis | 4.9 | 2.1 | 6.8 | 6.4 |
| Pleurisy | 2.7 | 3.7 | 2.9 | 2.6 |
| Pneumonia | 82.5 | 105.5 | 89.1 | 82.1 |
| Puerperal septicæmia | 12.6 | 10.2 | 12.5 | 15.7 |
| Scarlet fever | 20.9 | 3.9 | 24.0 | 30.1 |
| Scrofula and tabes | 6.2 | 16.0 | 2 7 | 2.6 |
| Still-born | 36.4 | 39 6 | 24.7 | 34.9 |
| Suicide | 3.2 | 0.5 | 2 7 | 7.2 |
| Tetanus and trismus nascentium | 3.1 | 9 3 | 1.6 | 2.2 |
| Venereal diseases | 1.7 | 3.0 | 1.4 | 1.3 |

The influence of race upon mortality is especially manifest in the death-rates of cancer. The number of deaths from cancer per 100,000 population in certain portions of the United States, with distinction of white and colored, was as follows: White, 27.96; colored, 12.67.

In the northern part of the United States the proportion of deaths from cancer in proportion to 1,000 deaths from known causes, with distinction of white, colored, Irish, and German parentage, was as follows: White, 19.1; colored, 7.8; Irish parentage, 24.3; German parentage, 25.8.

It will be seen from these that the liability to death from cancer is not half as great among the colored people as it is among the whites, and that there is a greater tendency to death from cancer in persons of German parentage than in all the average white population, especially between the ages of fifteen and sixty-five.

The relation of race to vital phenomena in general, and to disease- and death-rates in particular, forms one of the most interesting branches of what Galton calls the "science of heredity," but it is a branch in which little progress has yet been made, and for the study of which the United States offers greater opportunities than any other country. "The question of race influence is not merely an abstract matter fitted only for well-rounded periods in the discussions of the schools, but it profoundly affects vital and national life." It is a force which acts incessantly upon and menaces us, and, so far as we can now see, it is mainly upon the outcome of the distribution and prevalence of race that depend civilization, religion, and the future of man upon this earth. "In so far as the conditions of things tend to preserve the best types, progress is favored. In so far as they tend to destroy or to debase them with inferior types, progress is hindered. Not every mixture of race prevails, or persists, but there has been a certain amount of mixture wherever there has been progress in human affairs. Such mixture appears to have been a consequence rather than a cause, yet it may become an important secondary cause in changing or modifying the course of human events."

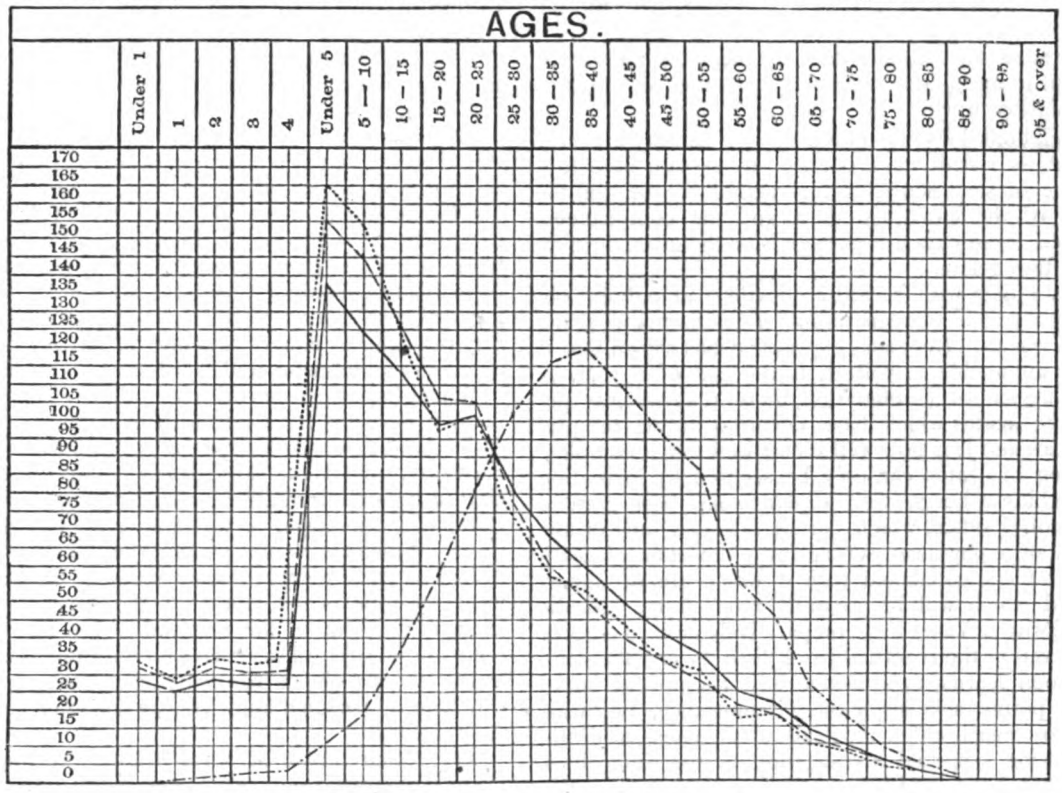
The census gives us a view of the population on a certain day, and, if well taken and properly compiled, it gives a general view of the stream of life as it flows on that day, with its variations of breadth and depth, from which it is possible to calculate, within certain limits, the velocity of the current, the rapidity of change, and the probable rate of increase or decrease, especially if comparisons can be made with the results of a previous census taken in the same way. It may also indicate periods of wide-spread disaster or of migration. For example, look at the diagram on opposite page, showing the proportions of the living population in 1880.

It shows that the decrease in the number living at each quinquennial group of ages was tolerably regular for the whole population for the native-born whites and for the colored as we proceed from the lower to the higher ages, as it should be under ordinary circumstances; but that there is one marked exception for the age-group 15 to 20, in which the line makes a sudden angle indicating a relative deficiency in the number of persons living at this age.

It will be observed, also, that the age-group in which there is the largest proportion of the foreign-born population is that from 35 to 40.

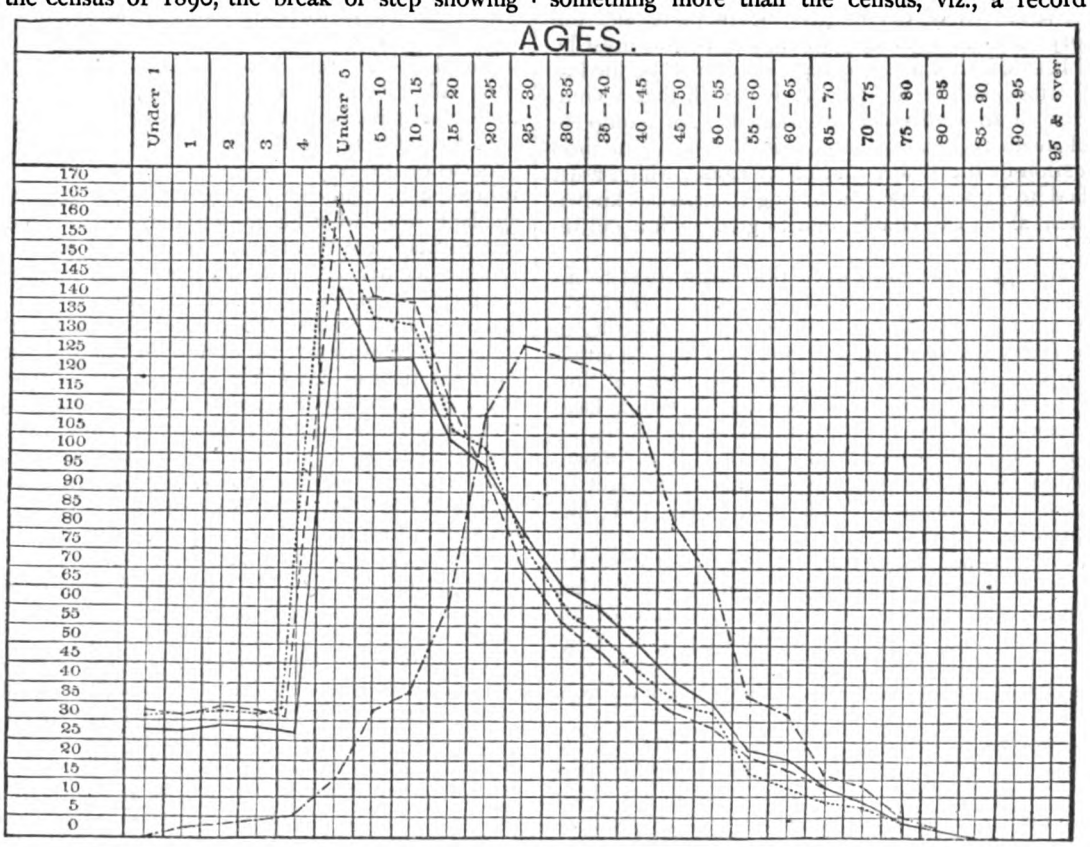
Now, if we compare this diagram with a corresponding diagram for the census of 1870, we find that this peculiar deficiency in the age group, and the maximum proportion of the foreign-born, occur in those age-groups which precede by ten years the groups in which they occurred in 1880. The break or step in the descending line is in the age-group 5 to 10, instead of that of 15 to 20, and the maximum proportion of the foreign-born is in the age-group 25 to 30, instead of that of 35 to 40. Now, if we go back between five and ten years from the census of 1870, to see what special cause existed in that period for a diminution in the number of births, we find ourselves in the period of our civil war. These breaks or angles, then, are the scars of one of the wounds which the war inflicted, or, rather, they are like the spots and ridges on the finger-nails due to serious illness or local injury, which gradually grow out and disappear. The shifting of the maximum point in the line of the foreign-born population indicates

the unusually great immigration of Irish and German families containing young children, which occurred between 1850 and 1860, forming a wave whose crest is still perceptible. It is safe to predict that in a similar diagram for the census of 1890, the break or step showing deficiency in births will be shifted forward to the age group 25 to 30, and that the maximum proportion of the foreign-born will be in the group 45 to 50.



Proportion, in 1,000, of Living Population at Certain Groups of Ages, at Census of 1880.[1]

In general, we may say that the census indicates the state of the population at a given period. Vital statistics, however, consider both the state and the movement of the population, and therefore for these we must have something more than the census, viz., a record of the deaths and births occurring in successive periods, from which we can compute mortality and natality rates.



Proportion, in 1,000, of Living Population at Certain Groups of Ages, at Census of 1870.[1]

Mortality, or mortality rate, refers to a ratio between the number of deaths occurring and the number of living population furnishing those deaths. It is to be distin-

[1] —— All classes; — — — — native white; - — - — - — foreign-born white; ..... colored.

guished from a statement of the number of deaths, since to determine the mortality in a given population we must not only know the number of deaths, but also the population furnishing that number. $M=\frac{D}{P}$.

In the same way, natality does not mean the number of births, but it means the ratio of the number of births to the population in which they occur. $N=\frac{B}{P}$.

The relations between mortality and natality are very important, as I shall have occasion to explain hereafter. The value of such statistics depends, of course, on the accuracy of the individual data, and the completeness with which these data are gathered for the given locality to which they relate.

Accurate data with regard to deaths can only be obtained by a system of registration of deaths made at the time they occur. Repeated experience has shown that it is utterly impossible to collect, at the end of a year, by any mechanism of enumeration, more than seventy per cent. of the deaths which have occurred during the preceding year, and it is now well recognized that a complete registration of deaths can only be secured by legislation which forbids a burial until a permit has been granted from a central office, which permit is issued only on the certificate of a physician, setting forth the cause of death and other facts connected with it which are of importance, and which will be presently referred to. In the great majority of cases it is comparatively easy to enforce the law, even in thinly settled rural districts, and the community soon learns to consider any attempt at burial without a permit as a suspicious circumstance, indicating a desire to conceal either the death or the cause of death, and justifying a special investigation by the authorities. When it has been decided to require a burial permit in all cases, it is not usually difficult to require the data for registration as an indispensable preliminary to the issuing of such permit.

Any system which depends upon the returns of undertakers for a record of deaths gives incomplete and unsatisfactory results. It is only where the permit must be obtained before burial and the certificate must be filed at a central office before the permit is issued, that a complete record of all deaths will be obtained. Any complete system of death registration should include some method of verification of the death and of its cause, which must be certified to by some person having the special knowledge which alone can enable him to give such a certificate.

In the first place, we must have this verification to insure the fact of a death having taken place. In its absence, in a large city, there is little or no difficulty in having recorded the death of a person who may be either alive and well, or non-existent, and the door is thus opened to frauds of various kinds, some of which have actually been attempted and discovered, while others, no doubt, have been successful and remain still unknown. Such verification is also necessary to insure the fact of real as opposed to apparent death in any case, and thus prevent premature burial.

The utility for this latter purpose is, of course, small, for the popular idea as to the frequency of trance or other conditions simulating death, so that the true state of affairs is not detected, is, as you all know, grossly exaggerated. Nevertheless, this consideration may enter as a factor into an argument in favor of such skilled verification.

The main reason, however, for the verification of a death by expert testimony as to its cause, is that it is necessary to establish the fact that a death has taken place from what may be called natural causes as opposed to criminal causes.

This verification of death, and of the causes of death, may be made either by physicians employed for that particular purpose and paid by the State, or by the physician under whose charge the deceased person has been immediately previous to death; in which latter case only those cases which have not been under the treatment of a physician are referred to a public medical officer, or the coroner, for verification and determination of the cause of death.

The first system is that which is employed in France, Austria, and Belgium. The second is the one made use of in England and in this country.

All registration laws include the certificates of physicians as an essential part of their machinery. Some do this directly, requiring that physicians shall keep a list of all deaths occurring in their practice, and shall forward this list at stated times to the registrar. This method has invariably proved to be a failure, as has also the similar attempt to require of clergymen that they shall furnish lists of the marriages which they have solemnized. It is utterly impossible to enforce such laws under penalties, and not fifty per cent. of either clergymen or physicians will carry out their requirements under ordinary circumstances.

Where burial permits are required, a physician may be made responsible for a certificate as to those matters only with regard to which his special professional knowledge is necessary, such as the cause of death, duration of sickness, etc.; or he may be required also to certify as to the age, birthplace, parentage, occupation, etc. The great majority of physicians accept without hesitation the data furnished on these points by some member of the family, or whatever appears set down in the form of certificate brought to them by the undertaker for signature. But there are always physicians who question the propriety of the law and object to certifying to that of which they can have no personal knowledge, while some few may possibly decline.

The requirements of a registration law impose upon medical men who sign certificates as to causes of death a very considerable responsibility, much more considerable, in fact, than many of them probably realize. The physician is to consider whether his knowledge of the case is sufficient to enable him to determine whether or not the death was due to what are called natural causes, whether there is reason to suspect that violence, poisoning, criminal neglect, etc., may have been more or less factors in the result, and whether any certificate as to the nature of the cause is justifiable. The pressure upon the medical man to certify to more, or sometimes less, than he knows, is occasionally very strong, but the only course in doubtful cases is to indicate clearly what one knows, as distinguished from what he merely believes on the faith of statements made by others. In ordinary matters of daily routine occurrence, in which there is no apparent motive for falsification, we constantly do, and must, accept the statements of others; the physician acts as the primary judge of the evidence submitted by relations and friends as to the time of death, the age and race of the decedent, the duration of the disease, etc., and is justified in certifying to his belief in this evidence, very much as he is justified in certifying to the date of his own birth.

It has been objected [1] that registration laws may do very well for countries where people have been trained for generations in that line of action, but that they are at war with principles of democratic action and with individual freedom, and that the reason why physicians do not execute the law is because they not only have no personal interest in its execution, but because of a feeling of revolt against the injustice of a law which inflicts a special tax in the shape of time and trouble, and affords no compensation for the extra labor and expense.

These views are not those held by the majority of the medical profession, and it is not probable that the payment of a fee would add much, if anything, to the completeness or accuracy of the registration data furnished by medical men. Nevertheless, these objections have some weight from a legal stand-point, and should be borne in mind in attempts at legislation. Any attempt to compel a physician, under penalty, to report the age and birthplace of his patients, would certainly be worse than use-

[1] Dr. H. M. Lyman, in the Chicago Medical Journal, 1878, p. 252.

less. The policy is not to call upon medical men to submit the information which should be demanded from the parent or householder. Under the police power of a State, certificates of the cause of death may be required from physicians as being necessary to secure life and protect property, but returns for merely statistical purposes, such as of births, cannot be required of any other than the parent.

There is no good reason why reports of births should be required from medical men. But as regards reports of deaths, it is to the interest of properly qualified members of the medical profession that such certificates should be demanded from them. Whenever and wherever certificates as to the cause of death are required from physicians, there must also be established some system of determining who are physicians within the intent of the law.

At first it may be necessary to accept certificates from anyone and everyone who chooses to call him or herself a physician; but the character of some of the documents of this kind, which will come in, will very soon indicate the necessity for some discrimination. Thus it is that the certification of the causes of death by physicians is the essential foundation, and it is the only essential foundation, of legislation with regard to the qualifications which the State has a right to demand from practitioners of medicine.

The registration of marriages, births, and deaths is important to the individual, because it gives him increased security in his rights to property and to life, by enabling him to furnish proof of parentage and legitimacy, by increasing the chance of detection of fraudulent claimants to property of which he is the true heir, and by discouraging criminal attempts to shorten his life, owing to the fact that evidence must be furnished that death was due to natural causes, or a special legal investigation of the circumstances will be made. Of the importance to the community as a means of protection of health and life, and to scientific men and physicians as a means of investigation of some of their problems, I need give no proof to this audience.

We can hardly be said to have a complete system of registration of births in any State or city in this country. Probably the city of Providence, R. I., has the most complete records of this kind of any of our cities. As regards the registration of deaths, Massachusetts, New Hampshire, Vermont, New Jersey, the greater part of Connecticut and New York, a large part of Alabama and Minnesota, and most of our large cities, have now a fairly satisfactory system and complete record. For the rest of the United States, there is either no system of registration, or, if any exists, it is a very imperfect and incomplete one, the results of which cannot be depended upon, and which cannot be compared with the results obtained in the localities above referred to as having a complete system; and the only means which we have of estimating the mortality of these localities is by the reports of deaths for the preceding year collected by the census enumerators.

It is for this reason that the decennial United States Census is a matter of such great importance to scientific medicine, and to practical sanitation—of much greater importance, in fact, than most physicians and health officials seem to fully appreciate. It is true that the death-records thus obtained in the large areas of the country in which there is no registration are incomplete, and, as regards causes of death especially, inaccurate; but they are the best we have; they are becoming better at each census, and the death-records in the registration areas serve to measure their reliability, and to indicate to some extent useful corrections.

As the value of statistics of deaths depends very largely upon the possibility of comparing them with corresponding statistics of the living population furnishing those deaths, it is evident that the modes and times of obtaining and of publishing the results of the census are matters of great importance to medical and sanitary statisticians. This is especially true as to the frequency with which a census is taken, the units of area made use of in its published tables, and the combinations of age, sex, race, and occupation data given in connection with such units of area.

Let us first consider briefly the time of taking the census.

The conclusions of the various statistical congresses with regard to the methods of the census are summed up by Korosi in his project for a census of the world, published in 1881.

The first of these conclusions was that the census should be taken every ten years, in the month of December, and in those years the number of which terminates in zero; recommending, however, that intermediary censuses should be taken at the discretion of different governments.

The taking of the census at the end of December has the advantage that a relatively greater number of population are in their own homes then than at any other time, and that it corresponds to the termination of the calendar year, at which date many State and municipal reports terminate, so that all the figures, being for one date, are readily comparable with each other. For a very large part of this country it would be quite as easy to take the census at the end of December as on the first of June; but there are some sections in which attempts to take the census in the midst of cold and rainy weather, for a thinly scattered population, would be made under very great difficulties.

In a paper read at the British Health Congress in May, 1889, Sir Edwin Chadwick urges the desirability of an annual census for the improvement of public administration, referring to the fact that, "in commerce and in manufactures, as in every large company, there is an annual stock-taking, and upon that stock-taking a report and declaration of the results is made to the stockholders. But what is the state of the political administration which has only attained to a stock-taking of the living people, of the healthy and the weakly, on whom the power and the prosperity of the county depend, which is only attempted every ten years, and is only completed in three years, leaving the numbers, meanwhile, to be got at by estimates, necessarily erroneous—often widely erroneous? An annual census of the more numerous animal stock has been lately striven for and attained, and is worked out by the Agricultural Department of the Board of Trade. It is some forty-five millions of the agricultural stock, while the population of England and Wales is about twenty-eight millions. Other nations, as France and the United States, have halved the inconvenience of the stock-taking of the human population."

Sir Edwin is in error in this last statement, for the United States Census is taken but once in ten years, and but a few States have thus far taken the intermediate census, which would make the enumeration come at quinquennial periods.

In the law providing for the last census, an attempt was made to induce the States to take this intermediate census by an offer that the United States should pay one-half of the amount paid to all supervisors and actual enumerators in the State, increased by one-half of the percentage of gain in population in the State, provided that the schedule used should be similar to those used in the census of the United States, and that a full copy of all schedules returned, and reports made, should be deposited with the Secretary of the Interior on or before the September following.

This provision, however, has not had the effect designed, probably for the reasons set forth in the report on the census of Michigan for 1884, namely, that at least two months are required to make the enumeration, transmit the blanks to the Secretary of State and arrange them, which leaves but one month (August) for correction of errors and for making the full copy of the schedules. As applied to the State of Michigan, this would require a thousand or twelve hundred clerks for twenty-five days. The amounts paid the supervisors and enumerators for the United States Census of 1880 were $71,192.06, one-

half of which, increased by one-half percentage of gain, gives $42,401.99 as the amount Michigan would have received from the General Government if its census had been taken in conformity with the national census law. But it would have cost from sixty to seventy thousand dollars to copy the schedules and reports, or from eighteen to twenty thousand more than the amount that would have been received from the national treasury to compensate for the work. A few sets of territorial schedules were sent in, but nothing was done with them.

Sir Edwin, however, urges that even the quinquennial census would be considered insufficient for business purposes in the ordinary affairs of civil life, and refers to the fact that the proposition for an annual census in the European governments was discussed at the International Statistical Congress at the Hague, having been proposed by himself and strongly seconded by Professor Engle, the head of the Statistical Bureau of Prussia. The matter was appointed to be the subject of discussion at a future Congress, but in the meantime the meetings of the Congress were interrupted, and the matter has never again come up as a subject for international discussion.

Annual censuses have been tried and abandoned in Canada. Triennial censuses have also been tried, but the general conclusion seems to be in favor of five-year periods.

In Austria, Belgium, the greater part of the British Empire, Denmark, Holland, Hungary, Italy, Norway, Sweden, Switzerland, and the United States, the census is decennial.

In the Sandwich Islands a census has been taken every six years since 1853.

In France a census was taken in 1801, 1806, and every five years since 1821.

In Sweden every five years from 1775–1860.

In Germany every five years since 1866.

In Finland every five years since 1875.

In Sweden every three years from 1749–75.

In Baden every three years from 1818–67.

In Hanover every three years from 1830–64.

In Prussia every three years from 1834–67.

In Saxony every three years from 1834–67.

In Bavaria every three years from 1834–67.

In Upper Canada (now the Province of Ontario) a census was taken annually for nineteen years from 1824–42.

In New Zealand nine censuses have been taken since that of 1851, at intervals of from three to seven years, the last interval being five years.

In Queensland there is also a quinquennial census.

While it is not probable that any agreement for an annual census of the whole country will be made in the near future, either by the United States or by State governments, it is certainly quite possible that the desirability for more frequent enumerations in the larger towns and cities will soon become so evident as to lead to systematic arrangements for carrying it out. Even now, many cities take what they call a police census, at irregular intervals of from three to five years, for the purpose, mainly, of making rough subdivisions of the voting populations in the form of precincts, and of obtaining information for the purpose of levying taxes, more especially for school purposes. These police censuses, however, relate only to adult males, and upon them are based estimates of the number of the remaining population, which are used by the sanitary officials in computing death-rates. These estimates, however, are almost invariably too high, as is shown by the next State or National census, and, in any case, afford no satisfactory basis for computation as to the number of inhabitants in the different wards of the city, owing to the great variations in the ratio between the voting population and the rest of the people in different classes of society and in different parts of a town.

By the use of proper schedules, somewhat on the English system, left at each house, there should be very little extra expense over that of the ordinary police census in collecting sufficient data with relation to the entire populaton of a city, to give accurate data with regard to the vital statistics of the population, and these, combined with a good system of registration of deaths and marriages, would give the means for a system of vital statistics of a place such as, at present, no city in England or in this country possesses.

The unit of area made use of in furnishing the census data is a very important matter in connection with the statistics of deaths, for, practically, these last must be classified by the same areas. The census units of area have usually been fixed by political considerations with reference to votes, to taxation of various kinds, and to military service. In this country the smaller unit is usually the county or city, or, in some cases, the wards of a city, the larger units being the State or Territory.

For the purposes of vital and medical statistics such units of area are often of little or no importance, because the boundaries of wards, of cities, of counties, and of States are not fixed with reference to the peculiarities to topography, drainage, character of habitations or of the people, which are important factors in the causation of disease and death, and which, therefore, require study, as much so as with reference to dividing the population for purposes of representative government. Moreover, in the publications of the several censuses prior to that of 1880, the population of the smaller areas, such as cities and counties, was, as a rule, given with distinction of sex and of color only, while the most important factor in vital and medical statistics, namely, age, was stated in detail for States only. In the census of 1880 an important advance was made in this respect, for, in connection with the mortality statistics, the population of each county having ten thousand inhabitants and upward, and of the large cities, was given with distinction of age under one year and under five years, for each sex of each color.

In the next census the population by counties will be given with still further distinctions of race; it will be given with distinction of age under one year and under five years for wards, and in about two dozen of the largest cities it is proposed to select certain areas which present peculiarities as to topographical features, or as to the character of the people inhabiting them, and to give the population of these by age, sex, and color, as a basis for the study of the death-rates of these localities. In a large city like New York, even the ward is usually too large to be a satisfactory unit of area for statistical study, since one ward will contain some of the best and some of the worst habitations, and include classes of people having very different means, habits, and death-rates.

In the annual report of the city of Brussels the population, births, and deaths, are given by streets, courts, and alleys. This does very well for Brussels, where the streets are short; but in our large cities, regularly laid out in rectangles, where the streets are miles in length, and traverse localities differing widely in topography and in character of population, it does not seem to be applicable.

The data required on individual certificates of death should correspond to those required on the schedules of living population, and, in addition, should give the cause of death.

The death-rate, or mortality, is the ratio between quantity of life and loss of life. It refers to a definite unit of time, viz., one year's life of one person, and the quantity of life is the sum of the time lived by each of the population expressed in years. Two persons living six months each, or twelve persons living one month each have one year of life. If the population is assumed to be stationary, that is, one in which the births and deaths, and the emigration and immigration, are exactly equal to each other and similarly distributed throughout the year, then the number of the population multiplied into the time under consideration, expressed in years and fractions of years, gives the quantity of life

A population usually, however, increases in geometrical

progression, and in such case we must find, by means of a well-known formula, the mean population of the period, which will be less than the arithmetical mean of the populations at the beginning and end of the period and greater than the population living in the middle of the period; but the differences are small, and, in most cases, either figure may be employed.

For example, suppose we wish to calculate the death-rate of New York City for the year 1888. By the censuses of 1870 and 1880 we know the population on June 1st in each of those years. From these we determine the ratio of increase, and thence the population on January 1 and December 31, 1888, from which the mean population can be computed, or the arithmetical mean be taken. Or, we can compute directly the population on July 1, 1888, and it makes little difference as to probable accuracy which of these three estimates of population we take.

You will perceive that this method rests on the assumption that the ratio of increase of a locality during ten years as determined by the census continues unchanged and uniform thereafter. This is hardly ever true, and, for many localities in the United States, and especially in the rapidly growing West, it is very far from the truth, which is a strong argument for more frequent counts.

Various methods are used by statisticians to correct the estimates of population made for a city at periods other than during a census year, as determined by a formula of arithmetical or geometrical proportion, among which may be mentioned the use of the ratios supposed to exist between the number of houses or the number of voters, or the number of school-children and the total population. The number of houses is determined from tax records or by a special count; the number of voters by registration lists or by a police census; the number of school-children by a special census; and the ratio which these bear to the whole population is guessed at or is calculated from the data obtained at the last census.

The most useful and reliable of these methods is the use of the average numbers of presumed occupants of inhabited houses, the other ratios being of very little value.

This has been very well shown by Dr. Russell, Medical Officer of Health at Glasgow, in a paper on "The Decennial Census as a Basis for Statistics in Intervening Years," Glasgow, 1881. In the case of Glasgow he considers the estimate of her population based on the number of inhabited houses and the estimate based on preceding censuses, and finds that both methods give a population above the actually existing one as shown by the next census. The error in the estimates based on the previous census was due to a change in rate of growth. The error in that based on the number of houses was due partly to incorrect data of the number of inhabited houses, and partly to an error in calculation.

In the United States Census of 1870 the number of persons in a dwelling in the large cities varied from 14.07 in New York to 5.20 in Toledo, these differences being due, to a considerable extent, to the counting of large tenement-houses containing numerous families as a single dwelling.

If we take the data by families, we find in the same census that the largest number of persons to a family was in Kansas City, the number being 5.78, while in New York it was but 5.07.

In 1880 the proportion of persons to a dwelling ranged from 16.37 in New York to 4.68 in Memphis. In Baltimore it was 6.54; in Boston, 8.26; in Philadelphia, 5.79. The number of persons to a family was: In Baltimore, 5.8; in Memphis, 4.23; in New York, 4.96; in Philadelphia, 5.13.

It is evident that no value can be placed on estimates of population of a city based upon the number of habitations it contains if a cottage and a tenement-house are to be equally reckoned as a habitation.

Estimates of the population based on police censuses, on the number of school-children, or on city directories, are of very little use, being, in almost every case, in excess of the truth. No general rules can be laid down for the estimation of the population of a city at a period between two censuses. It is a special problem in each case, for the solution of which there is needed an acquaintance with the locality, to be sure that boundaries have not changed, the information which can be obtained from special local censuses, from the number of inhabited buildings, from migration statistics, etc., all of which must be applied to the data furnished by the last general enumeration of the people, which, in any case, must be resorted to for the ratios which are to be used.

It is to be observed that municipal statisticians and registrars rarely make use of the means afforded by a general census to correct the figures of population, and, therefore, rarely alter death-rates which they have given for the years intervening since the last census; yet it is highly desirable that this should be done, in order to prevent the use of misleading figures. For example, in Chicago, in 1873, the registrar estimated the population of the city at 400,000, and deduced therefrom the death-rate for the year as 23.89. Comparing the populations in 1870 and in 1880, it was apparent that the true population was about 350,000, giving a death-rate of over 27.

In Boston, in 1876, the estimated population at the time was 352,758, giving a death-rate of 23.39, while the true population, as shown by comparison of census data, was about 313,000, giving a death-rate of over 26.

The shorter the period for which a death-rate is given, the greater is the liability to error. The ordinary forms of weekly death-rates reported for large cities are annual death-rates; that is, they represent what would be the annual death-rate if the proportion of deaths to the population for the week continued for one year. If, for example, a town having a population of 100,000 reports as its weekly death-rate for a given week 25 per 1,000, this does not mean that during the week there occurred 2,500 deaths, but it means that if the population and number of deaths each week are continued the same during the year, 2,500 deaths would have occurred in the course of the year, or that for the week in question the number of deaths was 2,500 divided by 52.17747. A weekly death-rate is useful to show where the greatest variations have been in the year's mortality, but it is no indication of the health of a town for a particular week, and it is useless as a means of comparison of the healthfulness of one town with that of another. This is largely due to the law of probable deviation or error in mortality statistics in relation to the number of instances used as data without reference to their accuracy. This law of probable error in relation to number of data is an exceedingly important one, to be kept in view in all statistical inquiries, and especially in those relating to vital and medical statistics.

For example, suppose that in a village of a thousand inhabitants there occur 25 deaths in the course of a year, and in a neighboring city of 10,000 inhabitants there were 200 deaths in the same time. What is the probability that the death-rate of 25 per 1,000 for the first, and 20 per 1,000 for the second, indicate the relative healthfulness of the two places, supposing the data to be perfectly accurate, and that we have no other information in regard to them than that stated?

Or, suppose that during one year, in a population of 100,000 persons, there occur 2,000 deaths, what is the probability that in a second group of 100,000 persons, under the same circumstances, the number of deaths in a year will not be less than 1,950, nor more than 2,050?

The answers to such questions as these are furnished by formulæ derived from the mathematical laws of probability. The simplest of all these formulæ, and the one most practically useful for rough and ready calculations in cases such as that given in the first example, is, that the mean or probable error is equal to the square root of the number of the dead. By this rule the probable error for the village of 1,000 inhabitants, for 25 deaths, would be 5, and therefore the mortality in this place might vary between 20 and 30 per thousand, without any certain indica-

tions of variation in the sanitary conditions of the place. In the city of 10,000 inhabitants, with 200 deaths, the probable error is a little less than 15, the variation between 185 and 215 corresponding to an average mortality of 18.5 to 21.5 per thousand, being a probable variation of only 3 per thousand instead of 10, as in the first case. It is very clear, then, that in comparing these two mortality-rates, no positive conclusion can be drawn as to the relative healthfulness of the two cities, seeing that the probable variations overlap, as it were, for the rates ranging from 20 to 21.5.

The formula that the probable variation in the number of deaths is the square root of that number, gives results that are somewhat too great, being merely an approximation to the true formula, which is of much more general application, but requiring too much computation for general use. I shall refer to this matter of the law of error in more detail in speaking of medical statistics. For the present, I only call your attention to the fact that it is necessary to bear in mind the absolute numbers as well as the percentages, and that, therefore, statements of ratios only are insufficient for definite conclusions.

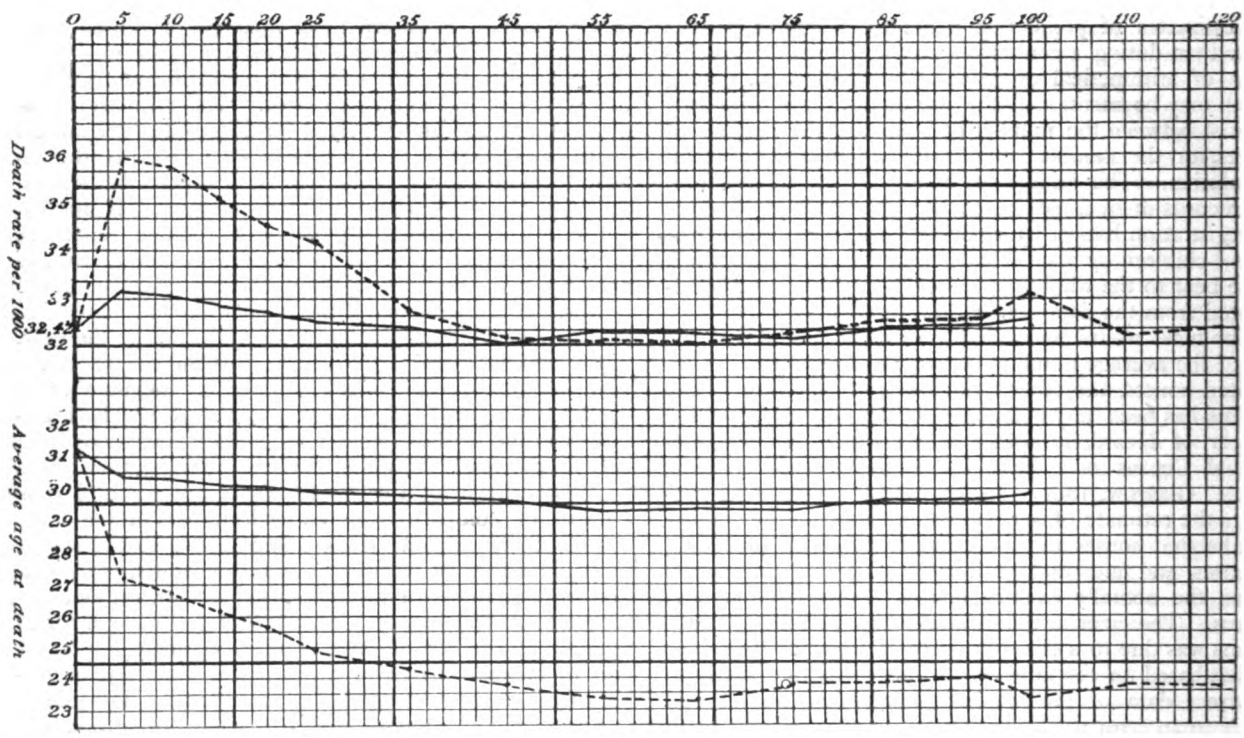
of an annual calculation of birth-rates and their comparison with the deaths of children under one year of age, or those born within the year. We can only obtain this data for any large extent of country by referring to the census records.

The usual method of indicating the birth-rate is by giving it as the proportion per 1,000 of births to the population of all ages; but a much better and more satisfactory mode of computation is to calculate the number of births to the number of women between the ages of 15 and 50 or 55 living in the community referred to.

The general subject of birth-rates is interesting chiefly in relation to social statistics, to the fecundity or rate of increase of population or of people of different races; but, in relation to mortality statistics, it may also become an important factor in the calculations.

There has been from time to time some controversy between statisticians and health-officers with regard to the influence of birth-rates upon death-rates, or as to the precise relations which exist between the two. As the death-rates of infants are much greater than those of the population at higher ages, it has been claimed by some that

*Diagram Showing the Effect of an Increased Birth-rate Upon the Death-rate, and the Average Age at Death.*[1]



What is a fair or normal death-rate? Taking an average healthy rural district in the United States, where there is little migration, the annual gross death-rate for the whole population will be from 13 to 15 per 1,000. In towns of from 10 to 15,000 inhabitants, having a good general water supply and proper sewerage, the gross death-rate should not exceed 16 per 1,000. In cities of from 20,000 to 100,000 inhabitants it should not exceed 17 per 1,000, while in cities of over 100,000 inhabitants it should not exceed 19 per 1,000. The great causes of high death-rates are poverty, overcrowding, intemperance, excess in heat and cold, with moisture, foul air, bad food, impure water, uncleanness, contagion, ignorance, etc.

Births and Birth-rates.—The statistics of births are of much importance in vital statistics, because of the influence of the birth-rate upon the sex and age-distribution of the population. Unfortunately, in this country, as I have already explained, hardly any locality possesses such an enforced system of registration of births as to permit

where there is a high birth-rate there also is a high death-rate; but it cannot be said that this will invariably be the case, or that the one is directly the cause of the other, except in certain cases for a comparatively short series of years. This will be best understood from the above diagram.

Starting with a population numbering in all 308,378, supposing that there are no migrations, we will calculate the progress of such a population for 100 successive years, under two suppositions—the first for a constant birth-rate of 35 per 1,000, and the second for a constant birth-rate of 45 per 1,000. The death-rate at the commencement say is 32.42 per 1,000. Under the influence of a constant birth-rate of 35 per 1,000, this death-rate will increase during the first period of five years to 33.17, and after that steadily sink until, at the end of 55 years, it becomes less than the original death-rate, and at the period of 65 years will sink below it; after which it again rises until, at the end of 100 years, it has reached the rate of 32.44.

Taking now the same population, under the same circumstances, at a constant birth-rate of 45 per 1,000, we see that the death-rate rises in the first five years to 36

[1] - - - - - - - Fixed birth-rate of 45 per 1,000; ——— fixed birth-rate of 35 per 1,000.

after which it steadily sinks as it did in the former case, until, after the lapse of 60 years, it is only 32.01, after which it again rises and finally comes down to a point a little below that from which it started. In both these cases, then, it is evident that the high birth-rate for a time produces an increased death-rate, since there are no other circumstances present to account for the change. But after the first five years the proportion of those living at the ages at which there is the lowest mortality has been so much raised as to more than counterbalance the large number living in the first years of life, and, therefore, the death-rate steadily descends.

But, to understand the full effect of this change, it is also necessary to consider the average age at death. Taking the average age at death at 31.37, it will decrease to 29.65 under the influence of a constant birth-rate of 35 per 1,000; while, with the higher birth-rate of 45 per 1,000, it will diminish as the death-rate diminishes to the age of 65, at which period it will be only 23.02, after which it will again rise as the death-rate increases.

As a rule, high birth-rates occur in cities, and in the crowded parts of cities, among the laboring classes of the population, where the causes of disease and death in infants are especially prevalent.

On the other hand, it is to be noted that a high death-rate among infants has some tendency to increase the birth-rate, because the interval between child-bearing is shortened by the early death of the infant; and in the effort made by poor women to avoid frequent child-bearing, a common means is to suckle the infant up to at least two years of age, in order to prolong the interval between pregnancies—which is a practice injurious both to the mother and to the child.

If we had under consideration a community in which there were no migrations, and in which the population neither increased nor diminished, the relations between birth-rate and death-rate and the average duration of life could be expressed by a simple formula, in such a way that, given either two of these quantities, we could determine the third. If, for example, in a population of 1,000 persons, five births and five deaths occur annually, and if we assume that every individual lives to the same mean age, evidently just 200 years would elapse before the whole of the original 1,000 would have died. This 200 years would be the mean duration of life, and this would be the case also if deaths occurred at different ages, only in such a case many would die below the mean age; when some would greatly exceed it. This subject has been considered by Dr. J. S. Bristowe in a paper "On the Mutual Relations of the Birth-rate and Death-rate."[1] From the table which he gives I have extracted that part which shows the mean duration of life under certain conditions of birth-rate and death-rate, where the birth rate varies from 3 to 5, and the death-rate from 15 to 35, in a thousand.

Dr. Bristowe says: "There can be no difference in the healthiness of two localities in one of which the death-rate is twice as high as that of the other, provided other conditions are such that in both cases the inhabitants attain the same mean age; or, conversely, supposing different populations to enjoy the same mean duration of life, any differences which may be presented by their respective death-rates are due to other circumstances than differences of health." He also says that the average duration of life can be determined by the birth-rate and death-rate taken together, but not from the death-rate alone. If he means by healthiness mean duration of life, this statement is equivalent to saying that, where the mean duration of life is the same it will be alike—an indisputable proposition, though not a very instructive one. But if by healthiness is meant the sum of the conditions of the locality as to altitude, drainage, cleanliness, etc., which tend to lessen or increase deaths in the people living in it, then the statement is incorrect, for it does not take into account age, sex, or race distribution, occupations, or migrations. Setting the question of migrations entirely aside, it is perfectly possible that two populations, attaining the same mean age and having the same death-rate, may live in two localities, one of which is decidedly healthier than the other; so that, if the two communities exchanged habitations, a marked difference in the death-rates and mean age at death would result.

Putting aside all these purely speculative considerations with regard to what might happen in a stationary population where there is no migration, let us see what the significance of death-rates is in our cities and rural districts, as they now exist. We wish to know how much of the death-rate is due to peculiarities in the character and occupation of the population itself, and how much to peculiarities in the locality, and for each of these classes we wish to know how much is necessary and unavoidable, and how much is due to causes which may be modified or done away with. Precise knowledge on these points we can never have, but we can obtain a sufficient degree of probability to guide our action in the premises.

If we wish to study carefully the influence exerted upon health and life by race characteristics, by residence in a given locality, by marriage, occupation, social standing, etc., we must have the means of comparing results given in different localities, or in the same locality at different times, or for different races, occupations, etc., under like circumstances.

To accomplish this we must, as far as possible, estimate the influence of other circumstances not connected with the particular point which we are investigating, but which, notwithstanding, exercise a powerful influence upon sickness and death-rates; and of these, the two most important influences are those which differences in proportion of sexes and ages of the population to be compared exert.

The means recognized as best calculated to eliminate the influence of sex and age, by, as it were, reducing the population to one uniform scale in these respects, is by calculating the expectation of life at each age for all the several conditions of locality, occupation, etc., which we wish to investigate; in other words, by the preparation of what are known as life-tables. A life-table shows what would be the tendency, or liability, to death at each age in a population in which there is no migration, and in which the births and deaths just equal each other, if such a population were subjected to the same influences tending to produce diseases and death as have affected the actual population under consideration, and from which the data are derived. It is, of course, impossible to prepare life-tables which shall be strictly accurate and exactly comparable one with another, because it is impossible to obtain strictly accurate data. A life-table is intended to answer the question, "Of a million children born, how many of each sex die at each age?" or, "What is the time which a man or woman of a given age may be expected to live?" A strictly accurate answer to this question could be given only if we knew the precise dates of birth and death of each of a million of children, born under the circumstances we are investigating; and, strictly speaking, these million children should all be born on the same day. Notwithstanding, by using large masses of data which are more or less attainable, and by applying certain well-known corrections, the individual errors tend to neutralize each other, and we can prepare tables which will be quite accurate enough for purposes of comparison.

A vast amount of labor has been expended upon, and study given to, this subject; for immense business interests and important points in the jurisprudence of inheritance depend upon the existence and accuracy of these tables. Hundreds of millions of dollars have been, and now are, invested in life insurance on the faith that certain life-tables truly represent the average course and duration of the life of a particular class of the community—and

[1] St. Thomas's Hospital Reports, New Series, vol. vii., London, 1876, p. 245.

the result of more than a hundred years of experience has been applied to their correction under the powerful stimulus of urgent need, from a pecuniary point of view, to have them as accurate and reliable as possible.

Probably the earliest form of such a table known is that given in the Pandects of Justinian by Domitius Ulpianus, commonly known as Ulpian, a distinguished lawyer, who was the secretary of Alexander Severus, and who wrote in the beginning of the third century of the Christian era. This table is found in an extract from his writings given in the Pandects in a treatise by Æmilius Macer.

Ulpian states that in Rome registers of Roman citizens, including the data of age, sex, and death, were kept by the city from the time of Servius Tullius to that of Justinian, including a period of one thousand years. From these data, which applied to the more prosperous class, Ulpian gives a scale for estimating the purchase value of communities according to the different values of life at different ages, and sums it up in saying that it is usual to compute thirty years' maintenance for all those under thirty years of age, and that for all over that age as many years are allowed as they lack of sixty.

In connection with the question of annuities, Ulpian gives a scale for estimating them, which is apparently the probable length of life of persons of the ages named.

The first life-table of modern times was constructed in 1692 by Dr. Halley, from the registers of the city of Breslau for five years, and was printed in the "Philosophical Transactions" in 1693. The data for this and for other similar tables constructed in the eighteenth century were too imperfect to permit of good results, and the first life-table which was selected as of sufficient accuracy for business purposes is what is known as the Carlisle life-table, compiled by Mr. Milne in the early part of the present century.

We now have a considerable number of life-tables applicable to the special classes of those who are likely to insure their lives, derived from the experience of a large number of insurance companies in Europe and in this country; and also a number of life-tables derived from the data of the whole miscellaneous population of the country for England, France, Germany, Sweden, and for certain parts of this country.

In order to prepare a life-table for a given locality or occupation, we must know the number of persons living at each year of age, and the number of deaths at each age which have occurred among these persons for one or more years.

We assume that deaths have occurred at regular intervals during the year for each age and proceed to compute the number of persons at each age, who were living in the middle of the period for which the deaths are registered.

In using census data, however, we cannot directly compare the deaths at each single year of age with the number reported by the census as living at that age, because of the strong tendency of the average man or woman to report ages either of the living or of the dead, but especially the former, in numbers which are multiples of ten or five, or in so-called round numbers. This will be seen by examining the census record of 1880, with regard to Massachusetts and New Jersey. The figures there given are for whites only.

An examination of these figures will show that the death-rates calculated from them would indicate that the mortality at 25, 30, and 40 is much less than at the ages immediately preceding and following them. Thus from the above figures it would appear that in Massachusetts the mortality of white males at the age of 50 is only 9.42 per 1,000, while at the age of 49 it is 16.11, and at the age of 51 it is 19.16 per 1,000. There is, however, no such abrupt change in the law of mortality at the age of 50 as these figures would indicate, and it is necessary, therefore, to make corrections for this source of error.

It is true that the error in the number of deaths reported at the even decades is usually in the same direction as the error in the number of the living population, and therefore tends to neutralize the error in the computation of ratios; but this is not always the case, as will be seen in examining the deaths reported in New Jersey for females at the ages 24–26; and as the ages of the dead are usually reported more accurately than those of the living, the error would be almost invariably in the direction of making the mortality at the even decades too low, and for the adjacent years too high.

The error in question may be corrected in distributing the excess reported at the even decades to the adjacent years, by aid of the calculus; but the easier and usual way is to calculate the mortality rates by groups of ages, including five or ten years in each group—that is, for the periods 20–24, 25–30, 30–34, etc., or for the periods 20–29, 30–39, etc., or for the periods 25–34, 35–44, etc. Of the three modes of grouping, the last is the best, because it properly distributes the excess about the even decades, which is the greatest.

If we take the group of ages 20–29, 30–39, etc., the whole excess for the year 30 is distributed in the succeeding years, whereas a part of it really belongs to the years in the preceding group. This objection applies to a much less degree to the grouping of 35–44, 45–54, etc., for the excess at 45 is much less than at either 30 or 40; still, it is well to remember that approximate life tables, calculated as I shall indicate, give for this reason somewhat less than the true mortality, and somewhat too high an expectation of life for adult ages.

This source of error affects all mortality statistics derived from the results of a national census, and from the ordinary system of registration, but it does not affect mortality statistics derived from the records of life insurance companies, in which it may be presumed that the ages of both the living and decedents are accurately stated.

I do not propose to describe the methods of constructing a life-table. To make one sufficiently accurate to be used for the purposes of life insurance requires elaborate calculations and corrections, and the use of complicated mathematical formulæ; but the construction of an approximate life-table, in which no attempt is made to secure regular gradation, is a comparatively easy matter, and has been fully described by Mr. N. H. Humphreys in a paper in the "Journal of the Statistical Society" for 1883, which method was made use of in calculating the approximate tables given in the mortality statistics of the last census.

A few words of explanation, however, are necessary with regard to the headings of columns in the specimen life-table which is before you. The column headed $Mx$ is the mortality or death-rate of each group of ages as shown in the left-hand column, which is obtained by dividing the number of deaths by the mean population of that age. It signifies the mortality at any age, or group of ages, $x$.

The column headed $Px$ indicates the probability of living a year at any given age, $x$.

The column headed $Lx$ shows the number surviving at each year of age out of a given number taken as a starting point. For example, during the census year, in New York City the births of males and females were in such proportion to each other that out of a million children born, 516,385 would have been males and 483,615 would have been females. Starting, then, with this number 516,385 males as living at birth, the age first in the column $lx$, we find that in the next year, by the action of the death-rate shown in the column $Mx$, this number has been reduced to 380,689.

The column headed $Qx$ shows the number of years which the persons who survive at that period of age will live after that age, that is to say, the total quantity of life remaining at any given age, $x$. From this is readily deduced the expectation of life; that is to say, the average mean after-lifetime of each individual.

## Life Tables.—Approximate Life Tables for Certain States and Cities.[1]

*Life Table for Providence, Boston, and Massachusetts, for Years 1883-1887, Inclusive, and for Following Ages.*

Such records as those which you see on the tables before you are the life of a nation or of a community. They are hard to get, and not easy to read in many cases, but nothing can take their place as a means of judging of the effects which circumstances are producing on the fertility, health, and vitality of the people.

(To be continued.)

Philippe Ricord was not only a medical specialist of the first rank, but a man of cultivated mind and refined tastes. He had a fine collection of works of art, and had a decided turn, if not for poetry, for graceful verse-making. Only about two months ago he composed a quatrain in honor of Mr. Edison's visit to Paris. He was one of the recognized wits of the French capital, and, like Falstaff, not only witty in himself, but the cause of wit in others. His encounter with M. Crémieux, at that time Minister of Finance, is well known. They met at a fancy dress ball, both being in the ordinary evening garb of civilized humanity. "You should have got yourself up as Plutus" (the God of Wealth), said Ricord to the Minister. "And you should have come as Mercury," was the retort.

## Progress of Medical Science.

THE PATHOLOGY OF EPIDEMIC DIPHTHERIA.—Criticisms and theories on this subject are always accepted as interesting if not instructive. Professor Bollinger has been working zealously at the subject of diphtheritic pathology, and more particularly the morbid changes occurring in the cells of infection and the cellular tissues. The change which first takes place is in the transformation of the nucleus of the cell affecting both the fluid and solid constituents, or its achromatic and chromatic properties. Repeated fission takes place till the entire contents of the cell are reduced to a fine granular consistence. Along with this a chemical change proceeds, ultimately transforming the nucleus and albumin of the cell into a fluid substance, which Bollinger designates as decomposition or necrobian change of the cell, that speedily reduces it to ruins. The cells that may escape destruction in this way will be observed to contain a number of nuclei, with no appearance to increase but rather to retrograde. This change in the cell substance appears to Bollinger to be effected by the absorption of the infecting poison from the fluid that bathes the cellular tissue of the throat and mouth, and the intensity depends on the amount of toxic material present. When this necrotic cell product is pent up in a large internal organ healing may take place by reabsorption, but when in the mucous membrane of the mouth and throat the cellular *débris* is poured out on the surface, forming the commonly observed pseudo-membrane, the mucous membrane at the places of exudation is consequently changed, the fibrous sheath beneath greatly infiltrated, and the walls of the blood-vessels undergo a hyaline degeneration, while necrosed particles of similar degeneration, fragmentary elements of cell destruction, with here and there a few healthy cells, are to be found in the deeper fibrous tissues. The bacterian research gives two different micro-organisms, the bacilli and micrococci. Of the bacilli there are long and short, as described by Löffler, while with the streptococci, diplococci, and tetrado of micrococci, Bollinger thinks there is proof of a compound mixture in diphtheritic infection composed of *specific bacilli* and *septic cocci*. Oertel, in discussing the pathogeny of diphtheria, attributes the disease to the decay and necrosis of the leucocytes, and the complete transformation of the cell element into a fluid consistence (hyaline degeneration), which he considers pathognomonic of the disease, although he does not deny the supposition that other diseases may assume similar changes. The infecting of other organs with the specific disease he assumes to be due to lymph transfusion, blood circulation, or the swallowing of diphtheritic products. He assumes the disease to be local in the first instance, and that after the destruction of leucocytes or cell elements the products of the *débris* become the vehicle of contamination. Bollinger concurs in Oertel's opinion, and expresses the belief that the ptomaïne arising out of the cell degeneration of bacterian vegetation which produces the pseudo-membrane is the chief communicating poison in diphtheria. From his own experiments he concludes that the pseudo-membrane, is the first outward sign of diphtheria, and that treatment should be specially directed to disinfecting the infected area by means of fluids or steam impregnated with some aseptic material. —*The Medical Press.*

RECURRENCE OF CANCER OF THE BREAST AFTER AMPUTATION.—From microscopic examinations of carcinomatous mammæ amputated by Professor Küster, Dr. Heidenhain predicted a return of the cancer in twelve cases, because parts of the morbid growth had remained in the wound. In the other cases he diagnosed a radical cure, which diagnosis had proved correct up to the date of the publication of his paper, because the operation had removed the whole of the morbid growth. The usual cause of the recurrence is that only microscopic parts of the gland or the tumor remain on the surface of the pectoralis major. In thin women the whole mamma is firmly attached to the muscle, but in obese subjects small glandular lobules are generally attached to the fascia between the mamma and the muscle, so that in amputation above the muscle small particles of gland may easily be left. Every mamma in which a single cancer node is found, according to Heidenhain, is largely, perhaps *in toto*, diseased. He found the epithelial cells of the acini proliferating in all parts of the mamma, and observed hypertrophy of the periacinous connective tissue, and he believes that these acini remaining in the wound form the origin of late secondary growths. In the retro-mammary fat there are, side by side with the blood-vessels, lymphatics leading from the mamma to the subjacent fascia, and the latter were, in two-thirds of the cases, full of metastatic cancerous masses. The pectoralis major itself is only affected when a metastatic cancer-node invades the muscle from the fascia, or the original tumor attacks it by its own simple growth. Heidenhain concludes that, to make amputation of the mamma more successful, it is necessary, even in freely movable carcinomata, not only to remove the whole mamma, but also a superficial layer from the whole of the pectoralis major, and in tumors which are closely connected with the muscle to entirely extirpate the latter.—*The Lancet.*

EXTIRPATION OF PELVIC TUMORS BY PERINEOTOMY.—At the last meeting of the German Gynecological Society, Dr. Sänger, of Leipsic, said that by the name perineotomy he meant the exposure of the ischio-rectal fossæ by the peritoneum for the removal of cysts, hæmatomas, exudates, or other tumors having their seat in the connective tissue and Douglas' cul-de-sac. A year ago he performed such an operation on a woman aged forty-two, suffering from a retro-rectal and recto-vaginal dermoid cyst. This woman has been obliged in her last six labors to have the help of a physician on account of the great development of the tumor. He made an incision of three inches, starting from the middle of the part separating the right labia majora from the anus and extending beyond this orifice; he penetrated into the pelvis, where he found a cyst having the size of a child's head; this cyst was independent of the ovary. The patient was cured perfectly. Only ten cases of the kind has he been able to find in the literature of the subject.—*The Medical News.*

TREATMENT OF HYDRARTHROSIS OF THE KNEE.—Dr. Georges Berne has adopted a plan of treatment of synovial effusion, in those cases which resist the usual methods of treatment, which has proved very successful. The treatment consists of a forcible rupturing of the synovial sac, which he terms *éclatement*, and which is followed by massage. The knee is semiflexed, when it may be noticed that the fluctuation is more marked above and inside the knee; the fluid is circumscribed, and the tumor formed is rendered tense by pressure with the hand; firm pressure with the thumb, or percussion with the edge of the closed hand, will produce an indentation, followed by a diminution of fluid effused. There can be no doubt but that a rupture or fissure of the synovial sac takes place at its weakest point—perhaps at the level of its insertion; the fluid permeates in the neighborhood of the lymphatics and veins, which are so abundant in the cellular tissue surrounding the joint. The rupture is easily effected in recent cases, as the membrane has not become thickened, and possibly the effusion is more liquid. After the *éclatement* massage must be persevered with, directed from the knee toward the groin, the form of massage being strong and deep centripetal pressures. The method is as free from danger as it is simple in execution.—*Provincial Medical Journal*, October, 1889.

HEREDITY OF INFECTIVE DISEASES.—The question whether pathogenous bacteria pass over from the mother to the fœtus has long been the object of scientific investigation. For this anthrax has offered the most attractive

field. The subject has again lately gone under review by Professor Max Wolff (*The Medical Press*). In 1858 Brand inoculated pregnant sheep, the mother died, but the progeny escaped. In 1869 Davaine, and in 1876 Bollinger, obtained like results. Since then Strauss and Chamberland, who have worked in a different way, have obtained different results. Professor Wolff's inquiry was made with a view of clearing up the doubt that has been raised by the experiments of the two previous investigators. His inquiry consisted in infecting some pregnant guinea-pigs, and later on examining the organs of the progeny after the mothers had succumbed to the disease. In every instance the results were completely negative as regarded microscopic examination; 150 cultivations were then made from the 29 fœtuses, and of these 144 showed no development of bacilli. In 6 such development was obtained. Finally, 29 control animals were inoculated from the 29 fœtuses, of which 26 escaped, and 3 were attacked by the disease and died. Particular attention was paid to the presence or absence of the bacilli in the placenta and membranes, with the result that, although they were found to be abundant in the maternal placenta, they were not once observed in the chorionic fringes. A second series of experiments was made with regard to vaccinia, 20 pregnant women were vaccinated, 17 successfully. The children themselves were vaccinated from one to six days after birth, and all successfully, a proof that the protection afforded to the mother by vaccination does not pass to the child, even when *in utero* at the time that the vaccination is performed. He finally attempts an explanation of the undoubted fact that small-pox is sometimes communicated from the mother to the fœtus *in utero*. He thinks infection may take place in one of two ways, either by hemorrhage taking place in the placenta, by which some of the maternal blood containing the variolous germs may enter bodily into the fœtus, or, in other cases, by contiguity.

On the same subject *The Lancet* says, in a recent issue, the question of the possibility of the direct transference of the virus of infective diseases from the maternal to the fœtal organism has, since the recognition of the apparent dependence of such diseases upon the presence of microbes, given rise to more than one series of experiments, and some interesting clinical and pathological observations. Among the latter is a case recorded by Eberth, in which the possibility of such transmission of the typhoid bacillus was raised. It was the case of a young woman, who, in the third week of an attack of typhoid fever, aborted at the fifth month. The fœtus was expelled within its membranes intact, and macroscopically appeared normal; but in the blood, and in fluid expressed from the spleen and lungs of the fœtus, there were found typhoid bacilli (recognized microscopically and by cultivation), which also occurred in the intervillous spaces of the placenta. Drs. Eug. Fraenkel and F. Kiderlen record a very similar case, in which, however, the abortion (also at the fifth month), though occurring in the third week of an attack of typhoid, was associated with acute peritonitis, found to be due to an ovarian abscess and double salpingitis. The placenta, fœtal blood, and spleen were examined for typhoid bacilli, but with a negative result. On the other hand, cultures of staphylococcus pyogenes were obtained from the spleen. This case harmonized with some others where there was a similar absence of the typhoid organism in the fœtus; but it is pointed out that in all these cases the placenta was normal. It would seem (as in Eberth's case) that the placenta must be diseased for such transference of pathogenic organisms to take place, and the occurrence of hemorrhage in the placenta appears to be a favorable condition for the transference. In this case, however, although typhoid bacilli were not transmitted, septic organisms were derived doubtless from the suppurating foci in the mother, and probably caused the death of the fœtus from septic infection. Fraenkel, about two years ago, injected subcutaneously cultures of the bacillus typhosus into three guinea-pigs. Two of them died in three days. They were both pregnant, and the fœtal part of the placenta was found to be hemorrhagic. The placenta and the fœtuses yielded abundance of the microbes. There have been other and contradictory observations on this subject of the transmission of microbes from mother to fœtus; some asserting it to be usual, others that it requires special favoring conditions. Netter found pneumonococci derived from the mother in a seven-months fœtus; Tizzoni and Caltani found comma bacilli in the blood and serum of a five-months fœtus. The observations are, however, too scanty to permit as yet of the formulation of any definite notions on the subject.

Chronic Tubercular Endometritis.—Dr. Jouin says that this form of tuberculosis is more frequent than tuberculosis of the other mucous membranes of the genito-urinary apparatus. This may be due to the fact that the mucous membrane of the body of the uterus is soft, spongy, and rich in tubular glands, these conditions being favorable to the development of an anærobic parasite. It has been observed and described to a certain extent by Louis, Aran, Bernutz and Goupil, and Verneuil, but the primary form has not been distinguished with sufficient clearness from the secondary by any one of these writers. Fernet described primary genital tuberculosis in a female, and spoke of its origin from sexual contact with a tuberculous man. Cornil and Chantemesse have also produced it artificially in rabbits by the injection of bacilli into the vagina. The author's studies included nine cases, in two of which the disease followed sexual intercourse with men suffering from genital tuberculosis. In two others the husbands were tuberculous, but had no apparent genital tuberculosis. In three others the cause could not be ascertained, and in the remaining two the cause was also uncertain. The diagnosis was verified once by the microscope and twice by the peritoneal inoculation of guinea-pigs. The disease is primarily a tubercular degeneration of the endometrium, but the uterine parenchyma and perimetrium may also be involved. The predisposing causes may be heredity and bad general condition, also ruptures of the cervix and repeated attacks of inflammation. The determining causes are the bacilli and sputa upon soiled linen, or even upon various instruments, and especially sexual relations with a tuberculous husband. The fungosities upon the endometrium in these cases contain bacilli, with which guinea-pigs have been successfully inoculated. As to symptoms, the patient is the subject of leucorrhœa, pain in the abdomen, scanty micturition, constipation, and sterility. After a time the uterus becomes much enlarged and very sensitive to the touch, also more or less fixed. The cervix is red and perhaps ulcerated, and a sanious matter is discharged from the canal. The patients are much more prostrated than in simple endometritis, and have emaciation, fever, sweating, and arthritic troubles. Without proper care this condition will extend to the lungs, but it may be arrested by local treatment. The diagnosis is to be made by histological and microbiological examination, but also by observing certain clinical phenomena. The disease does not begin after labor nor after blennorrhagia; the patient may not have had children, and the lungs may already present tubercular lesions. The primary form of the disease is not serious if properly cared for; the secondary form implies tubercular disease elsewhere. In treating the disease the patient should first receive creasote. Curetting may be practised, if thoroughly done, and the mucous membrane should then receive an application of creasote. Pencils of iodoform may also be introduced into the uterus, the organ having first been well dilated. This should be repeated every twelve days. Sexual intercourse should be abstained from as long as the disease continues. The hygienic and dietetic conditions must, of course, be as favorable as possible.—*The New York Medical Journal.*

The Use of Strophanthus in Children.—Dr. Demme has made a study of this subject, and has formu-

lated the following conclusions (*Archives of Pediatrics*, October, 1889). 1. Strophanthus, especially in the form of the tincture, may be given to children after their fifth year. In exceptional cases its use is followed by dyspeptic troubles. But as this agent in large doses may paralyze the cardiac muscle suddenly and unexpectedly, it should not be given in larger than three-drop doses, four or five times daily. 2. The predominant action of strophanthus is to increase diuresis, and consecutively to diminish the phenomena of venous stasis. This effect is produced by an increase in the blood-pressure, and is especially evident in connection with valvular lesions of the left auriculo-ventricular orifice, while the strophanthus does not, like digitalis, determine a compensation of the valvular lesion. In affections which are accompanied by exaggerated or even normal arterial pressure, the diuretic action of strophanthus is wanting. 3. Strophanthus also exercises a remarkable influence upon dyspnœal phenomena. This is due to the action which it also exercises upon the respiratory centres, and is seen in cases of chronic nephritis, and in such other diseases as bronchial asthma, whooping-cough, etc. 4. While there are great analogies in more than one respect between the effects of strophanthus and those of digitalis, each one possesses its own peculiar therapeutic action. Digitalis will be indicated in cases in which one wishes to obtain with rapidity a compensation for valvular lesions, with augmentation of the blood pressure, slowing of the pulse, and exaggeration of the urinary secretion. If digitalis does not produce these desired effects, they cannot be obtained with strophanthus. On the contrary, when a valvular lesion has been compensated by the use of digitalis, and it eventually becomes necessary to act anew upon the heart, in order to obtain a new increase in the blood-pressure, and a new increase in diuresis; when, in addition, dyspnœa becomes an urgent phenomenon, strophanthus will give excellent results. In such cases the combined action of digitalis and strophanthus will be indicated. 5. In no case did the author observe cumulative effect, nor weakening of the action of strophanthus, even after it had been used for a long time.

Antifebrin in Tonsillitis.—Dr. Sahli has found, both from personal experience and from numerous observations on patients, that moderate doses of antifebrin will almost invariably give great ease in cases of acute tonsillitis, thus allaying the distress of the patient, and enabling him to swallow food, stimulants, or medicine. The dose he employs is seven and a half grains, which he usually orders in a mixture with spirit and sirup, which must be shaken up before being taken. This is sufficiently agreeable to be taken readily even by children. Dr. Sahli mentions that he has found great benefit from this treatment in scarlatinal sore-throat.

Reproduction of Gastric Mucous Membrane.—The power of reproduction with which the mucous membrane of the stomach is endowed is considerable. Professor L. Griffini and Dr. G. Vasalle, after a series of experiments upon fifteen dogs, formulated the following conclusions: 1. The mucous membrane of the fundus of the stomach, removed in dogs, for a considerable extent and in its entire thickness is always reproduced, including the peptic glands. 2. The newly formed glands are developed from the new epithelial layer which in the beginning covers the wound. This epithelial layer itself is developed from the epithelium of the glands upon the borders of the wound, thus demonstrating the possibility of the development of an epithelial layer in its totality from true glandular epithelium. 3. The pepsin cells of the newly formed tubular glands are developed in the beginning through a differentiation of the cells of the tubular glands themselves, and this formation originates in the bottom of the tubules, whence the cells are pushed upward. 4. The reproduction process of the peptic glands finds its exact prototype in the process of embryonic development. 5. The reproduction was quite rapid in all the animals, which were strong and healthy and placed amid favorable surroundings. In one case the development was tardy, owing to a considerable loss of tissue and an unsuitable diet. 6. Perforation of the wall of the stomach never followed removal of the mucous membrane, even though the muscular tunic had been seriously injured.—*The Medical Bulletin.*

Asthma and the Uterine System.—Dr. Peyer has recently written on an affection which he terms sexual asthma. He maintained that asthma was always neurotic, and that in different subjects asthmatic convulsions were brought on by the influence of different physical functions. In two young married women coitus caused violent attacks of asthmatic sneezing. In another case the patient suffered from uterine fibroid, with severe asthma, which disappeared after the removal of the tumor. A patient was subject to violent asthmatic fits; on her becoming pregnant for the first time, the asthma was completely cured. In a similar case of asthma, the patient suffered from chronic metritis. When the uterine affection was cured, the asthmatic complication disappeared. In all Dr. Peyer's cases the patients were more or less hysterical, and in two there was a distinct family history of neuroses. The physician must be careful now to distinguish between the possible coincidence of true asthma and disease of the sexual functions and the alleged form where the former is an effect of the latter. In the case of coincidence it is perfectly easy to understand that any aggravation of uterine or ovarian disease and any irritation of the sexual functions might aggravate the asthma. The other condition is less easy to understand, and very hard to prove in a scientific manner.—*The British Medical Journal.*

The Ultimate Results of Extirpation of the Uterus.—Dr. Munchmeyer, of Dresden, said that at the obstetrical clinic of Dresden, from 1883 to 1889, there had been performed 110 extirpations of the uterus, of which 80 were for carcinoma and 30 for other diseases. Out of the 80 operated on for carcinoma, 4 died from the immediate effect of the operation—that is, five per cent.; 1 died from strangulated hernia, 2 from septicæmia, and 1 from peritonitis. Out of these 80 operated upon, 10 died from a recurrence of the disease, 4 of intercurrent affections, while others have had one recurrence. Forty-one who have been operated upon during this past year have had no return of their trouble, and in 17 women operated upon two years ago the cancer has not reappeared. Among this last series 3 have had no recurrence for three years, 1 for four years, and 1 for five years. He thought it very important that the operations should be performed as early as possible. Out of the 30 other extirpations, 17 were for myomas, 5 for prolapse, 5 for severe nervous troubles, 3 for diseases of the annexes of the uterus. Most of them were operated on by the vaginal method, or supravaginal. The vaginal method leaves patients in a state in which they are less liable to take cold; and, on the other hand, certain women cannot resist an abdominal incision, which is due to a weak state of the cardiac function. Out of 110 extirpations of the uterus, there were only 6 deaths—that is, 4.5 per cent.—*Medical News.*

A "Vaccine" for Infantile Diarrhœa.—M. le Docteur José Triano, of Columbia, asserts that a drop of balsam of copaiba, placed on the umbilical cord of newborn infants after section, protects them from athrepsia and choleraic diarrhœa. It acts as a vaccine, and is a certain prophylaxis for these affections. Previous to Dr. Triano's discovery, the infant mortality resulting from them in Columbia, like in France, was considerable, but now they have almost disappeared.

## ON ESSENTIAL TACHYCARDIA.

M. BOUVERET devotes a long article in the *Revue de Médecine* for September and October, 1889, to the description of a curious and, as he thinks, distinct disorder of the heart, viz., "essential paroxysmal tachycardia." It is a disease occurring in adults, and characterized by paroxysms of cardiac palpitation in which the pulse goes up to 200, 230, or even 300 per minute. The paroxysm lasts from a few hours to several days. If it is short the patient suffers very little distress. Absolutely no signs of organic cardiac disease are recognizable.

M. Bouveret reports three cases of his own in detail, in one of which death occurred. He succeeds in finding nine other similar cases.

Tachycardia is common enough but M. Bouveret insists that in "essential paroxysmal tachycardia" there is no organic disease, and moreover that it has the peculiar characteristic of being accompanied with few or no symptoms pointing to the involvement of other organs.

The cases which are collected have been reported by three English and five German physicians. We are under the impression that American observations have been made upon this subject but none are referred to by M. Bouveret.

From an analysis of the reported histories it is found that the attacks of tachycardia are of two kinds, viz., short and long. The short attacks come on with slight prodromes of vertigo, epigastric distress, etc. No cause is usually assigned. The pulse runs up to at least 190 or 200 a minute. There is a slight bruit often heard, while in place of the cardiac impulse one feels on palpitation a sort of vibration of the chest-wall. The patient becomes pale and suffers a little dyspnœa but feels no serious distress. The attacks cease abruptly.

The long attacks usually last five or six days, but may be prolonged several weeks.

The symptoms are much like those in the short attacks, except that after a few days the patient begins to suffer seriously from dyspnœa, cyanosis, and all the symptoms of heart-failure. Percussion shows, also, that the heart dilates very considerably. Among the eleven cases collected by Bouveret, four died during the long attack. In the other cases, however, the disease lasted a long time, and during the intervals the patients suffered very little.

The cases observed have occurred in persons ranging between the ages of nineteen and forty years, and the disease has attacked the two sexes about equally. The only important etiological factor noted has been excessive mental and physical strain.

Only one autopsy has been made upon the victims of this malady, and in that case no lesion was discovered either in the heart or nervous centres. Bouveret excludes any bulbar lesion, for the reason that in all cases of rapid heart-beat, due to such a cause, there are other symptoms, and in addition, the pulse-rate does not go above 150 or 160.

Dr. Bouveret cites cases of paroxysmal tachycardia due to organic disease of the heart, to gastro-intestinal disorders, and to uterine and ovarian disease. He also recognizes those forms of tachycardia described by Riegel and by Rosenbach, in which there are associated pulmonary and abdominal symptoms.

But he believes that there is a special type of tachycardia in which the only primary symptom is the rapid heart-beat.

The treatment recommended for the attacks is rest, digitalis, and a trial of compression of the pneumogastric in the neck. One patient could abort or relieve the tachycardia by taking a deep breath and holding it. In the long attacks, with much cardiac dilatation, venesection is suggested.

## ENOPHTHALMUS TRAUMATICUS.

THIS condition—a sinking back of the eye into its socket—is apparently very much less frequently observed than the contrary condition of exophthalmus. Apart from those cases in which it is seen in cholera, six writers have published notes upon it, each having seen only one case. In the *Archives of Ophthalmology*, September, 1889, a translation is given of a recent article by Dr. Gessner, in which he describes and discusses three cases of enophthalmus of traumatic origin, seen at the clinic of Dr. Nieden, of Prussia. The three cases presented very similar histories, of which one may be given as a specimen. A miner was knocked down and cut about the forehead by a piece of coal or stone. He was rendered insensible for a time, and was confined to his bed for three weeks, with swelling of the injured parts. When the swelling of the eyelids was sufficiently reduced to permit the eye to be seen, it was found that this eye was farther back in its orbit than the other, or, as the patient erroneously expressed it, "was smaller than the other."

Upon examination the affected eye presented the appearance of an artificial eye. A scar, the result of the injury, was found running from the incisura supraorbitalis (supraorbital foramen [?] ) to the corner of the lid. The upper lid was sunken, and drooped somewhat. The palpebral fissure was smaller than on the other side. The eyeball lay several millimetres deeper than normal. Its movements in an upward direction were slightly restricted, and in other directions they were sluggish. The cornea and other parts of the ball were apparently unaffected by the injury, and no change could be discovered upon ophthalmoscopic examination. Pressure upon the ball gave no pain. Vision seemed to be little or not at all affected.

The presence of microphthalmus could be excluded in each case by the equality of the cornea, the refraction, and also, in two cases, by the acuteness of sight in both eyes.

The enophthalmus was probably the result of wasting

of the retro-bulbar tissue, the sinking back of the ball being, perhaps, aided somewhat by pressure of the lids upon it. The contused wound of the orbital margin would naturally cause inflammation of the periosteum, which would spread to the cellular tissue behind the eyeball. Inflammation of the muscles of the eye need not to be supposed as the cause of the restrictive motion of the ball. The sluggishness of the muscles is explained sufficiently by their relaxation, caused by the sinking backward of the globe of the eye.

---

### NOTHNAGEL ON THE TREATMENT OF HEART DISEASE.

In an interesting clinical lecture upon the above subject (*Medical Press and Circular*) Professor Nothnagel discusses the various modern methods of treating heart disease, viz., the calomel treatment, the cardiac-tonic treatment, the hydriatric and the Oertel treatment. He speaks first of the use of digitalis and gives this drug preferably in the form of a powder with quinine, *e. g.*: ℞. Pulv. digitalis, gr. ss.; quiniæ sulph., gr. iss.; sacchar. pulv., gr. vj. M. Sig.: j. q. 2 h.

Nothnagel believes in the cumulative action of digitalis, and there is no doubt a final tonic effect when doses are kept up continuously every two hours. It is strictly enjoined, therefore, that this indication be not continued for more than five or six days. There is no drug equal to digitalis when the cardiac muscle is not seriously involved. If its effect becomes lessened, or it is necessary to stop its use for a time, the digitalis treatment may be alternated with a course of caffein. This drug is better given combined with a salicylate or benzoate of sodium, and it is prescribed by Nothnagel in doses of five grains five times a day.

Strophanthus is spoken of as a useful cardiac tonic, but less powerful and certain than digitalis.

Considerable space is devoted to the calomel treatment brought into notice by Jendrassik about three years ago. Nothnagel is convinced of its efficacy but ventures no opinion as to how the drug does its work. It should only be used in properly selected cases and should not be employed until digitalis has been tried. The following prescription is given: ℞. Calomel, gr. iij.; sacch. lactis, gr. viij. M. Sig.: j. four times daily.

Nothnagel says: "For three, four, or even five days the quantity of urine will remain unaltered, after which time it may rise from 300 c.c. to 7,000 c.c., *i.e.*, from *circa* one-third litre to seven litres (one-half pint to two gallons). In four days salivation will be produced, which indicates a withdrawal of the drug. Chlorate of potass or tinct. of rhatany as a gargle may be given. An unhappy complication is diarrhœa, for which opium must be given, but if constipation, jalap may be combined with calomel. My own experience of a surprisingly small quantity of urine passed, raised in a few days to 10,000 c.c., continuing at that for a few days till the dropsy disappears, and then gradually reducing the quantity leads me to believe in the efficacy of the drug. In many cases I found the calomel refused to affect the system, and in these cases the diuresis remained also unaffected, but after waiting six days I have repeated the mercury, when the effects were immediate. The opposite of this occurs also. I have had perfectly satisfactory results for the first time, but after that the physiological effects of the drug could not be produced. The improvement from this treatment usually lasts about eight weeks, when it may be repeated. I have had some cases where I have repeated this treatment eight times in a year with the best results, but alas! after a time the calomel becomes inert in the system, varying from one to a year and a half when it gradually becomes useless, and life soon ebbs away."

The Oertel treatment has for its object: 1, To reduce the amount of fluid taken into the body; 2, to gradually excite the muscles of the heart to contract.

"Most physicians," says Nothnagel, "are agreed to-day that this method of treatment is not for valvular disease. It is certainly excellent in dropsical conditions arising out of myocardy, fatty heart, so-called beer heart, idiopathic hypertrophy, or dilatation of the heart, in short, in all cases where the *muscle* of the heart is at fault, but not when the valve lesion is the cause. One factor in the treatment is to work the muscle of the heart and thus increase its muscular tissue, but where there is valvular imperfection there is much injury done by the treatment of Oertel."

If one is confronted, however, with a case of valvular disease, where compensation has established itself, but by some means or other the heart does not contract as well as it might do, and that œdema of the limbs, etc., is becoming ominous, the Oertel treatment may be tried to restore the disturbance by more hypertrophy.

As to the second part of Oertel's treatment, it is reasonably good. It is well known that a great amount of fluid swallowed must rapidly pass into the circulation, and load the heart and impede its action. To reduce the fluid taken in to the very minimum must have beneficial effects.

---

### A NEW ADVANCE IN THE TREATMENT OF UNUNITED FRACTURE.

Every surgeon knows how difficult it is in certain cases to get a broken bone to heal by bony union. The ends may be pegged and hammered and sutured indefinitely without success. In the case of fracture of the radius there are oftentimes special difficulties, since resection—the last resource of the surgeon—leaves a gap between the ends of the radius, which is now shorter than the ulna beside it, and so it is almost impossible to bring the bared ends of the fractured parts into apposition and to keep them there. Even if a piece be cut out of the unfractured ulna, so that the inequality in the length of the two bones is removed, a satisfactory result cannot always be obtained. In *The Lancet*, October 26, 1889, Professor McGill, after commenting upon the above facts and relating his failure with the last-mentioned procedure, explains a new method which he applied successfully in one case, taking the hint from a suggestion made by Dr. MacEwen, who proposed, in case of destruction of the shaft of the humerus by acute necrosis, that a new shaft should be secured by transplantation of bits of new bone.

In Professor McGill's case a man, twenty years of age, had fractured both bones so that the ends of the radius protruded through the wound on the radial side of the forearm. The ulna healed quickly and well, but the radius remained ununited, although the ends had been re-

freshed and wired three months after the accident. Some eight months afterward he came to the hospital. He had a scar over the wound, and the ends of the radius were quite movable, the usefulness of forearm and hand being much impaired. An Esmarch's bandage was applied and an incision was made in the line of the old scar. The ends of the bone showed no signs of union, but were rounded and covered by a thick membrane-like periosteum. When this had been filed away, an interval of three quarters of an inch was left between the fragments. This interval was filled with thirteen pieces of bone, each about one sixth of an inch in length, chiselled from the femur of a freshly killed rabbit. The bones were not wired. The skin-wound was tightly stitched, without drainage, with catgut. Firm pressure was applied by means of salicylated wool and bandages, and the forearm was placed on an anterior splint. There was no suppuration and very little discharge. The patient left hospital in six weeks, with the bone firmly united. Three months later the injured arm was as useful as the other. Is it not possible that this method used by Professor McGill may be of service in the treatment of old ununited fractures in other parts? It is possible that a more vigorous action might be set up, by presence of the implanted healthy bone, than would naturally occur in the fragments of a fractured long-bone in a person of feeble constitution.

---

## SANITARIA FOR CONSUMPTIVES.

Dr. Paul H. Kretzschmar gives an account of the development and work of the sanitaria for the treatment of consumptives in the United States in a recent issue of *The Medical News*.

Such institutions are, it is admitted, not as a rule necessary for wealthy persons, but those of moderate means can, in many instances, be best taken care of in special institutions where the therapeutic measures can be applied more cheaply on a wholesale plan. In Germany there are a number of hospitals in which consumptives receive treatment. The recent general acceptance of the infectious theory of phthisis has raised some protest against the aggregation of this class of patients, but we do not think that the objections made against them will stand. Phthisis is but very slightly contagious, and it seems to be admitted that those who contract the disease must have not only the bacillus but a favoring soil for its development. Besides this, the measures for preventing spread of the contagion have been carefully studied out, and are quite well known. The sanitaria for phthisical patients in this country, so far as known, are one at Saranac Lake, one at Asheville, N. C., one at Lake Palmer, Col., one at Colorado Springs, and a camping-out organization which has its headquarters at Santa Fé, New Mexico.

The results of treatment at the Saranac institution, as given by Dr. Trudeau, are certainly very encouraging. He says: Up to the end of 1888, 146 consumptive patients have been treated, and the results have been about as follows: Deaths, 4, or not quite 3 per cent.; failed steadily, 25, about 17 per cent.; stationary or slightly benefited, 38, about 26 per cent.; disease arrested, 63, or 43 per cent.; and cured, 16, or 11 per cent.

The results in the year 1888–9 are said to have been even still better, about 14 per cent. having been cured and 20 per cent. restored so that they could return to work.

At Saranac the main reliance is placed upon the out-door life. Among drugs, antifebrin and creasote are much used. The pneumatic cabinet is also still employed. At Asheville, oxygen inhalations are given, but creasote has been entirely abandoned, according to Dr. Kretschmar; while Dr. Detweiler constantly uses alcohol, it is not given at the Saranac institution and only moderately at Asheville.

The following rules, which are placed in the hands of every inmate of the sanitarium at Saranac Lake, can be read with profit by all who have phthisical patients to treat:

*Out-of-Door Life.*—Patients gradually accustom themselves to leading an out-door life, that is, to remaining eight to ten hours in the open air each day. This should be done gradually, and at first the clothing should be heavy and the exposures to cold or inclement weather moderate in duration. Little by little the open-air sittings and walks are to be increased until the entire day is spent out of doors in all kinds of weather. In stormy weather the sheltered side of the verandas should be used for walking or sitting. When feverish, patients are urged to go out and remain sitting on the verandas well wrapped in suitable clothing.

*Exercise.*—Violent exercise is injurious. When feverish, patients will do well to make as little exertion as possible. Fatigue, when induced in persons still having active disease, is sure to be followed by loss of appetite, fever, exhaustion, and even sweating. Severe exercise in hot weather is injurious and may be dangerous. Patients will be informed by the physician how much exercise their case requires.

*Food.*—If unable to eat at the regular meal hours, patients will do well to drink milk every four hours.

*Expectoration.*—Patients are required always to use the large spittoons in the public rooms and on the verandas, and the pasteboard ones in cottages; the latter should be burned every day in the stoves or fire-places. Expectorating in handkerchiefs or on the floors, or even on the grounds in the immediate vicinity of the buildings, is strictly prohibited.

It has been found that while moist sputum is harmless, when it becomes dried it will rise as dust, and may be inhaled. The above directions are given to guard against this result. Patients, for their own welfare and in order to assist in their rapid recovery, will strictly observe these rules, and will be liable to dismissal for wilful disobedience in this matter, which involves not only their own welfare but that of others.

*Stimulants.*—Stimulants are not allowed except under medical advice. No smoking is allowed at any time in the public rooms or on the piazzas. Patients are requested not to smoke at all unless permission is given by the physician.

---

As a Remedy against "Electrical Sunstroke," as the affection is called that attacks men exposed to the intense rays of the electric arc by means of which metals are fused and welded, is a veil or mask of glazed taffeta, supported by a wicker head-piece, and provided with goggles of gray glass.

# News of the Week.

SIR MORELL MACKENZIE has been vindicated by the Royal College of Surgeons. Though condemned by the Council of the College for publishing his book concerning Emperor Frederick, he had but one accuser at the general meeting.

THE PROJECT OF BUYING UP A COUNTRY for purely sanitary reasons, because it is a fitting one, is certainly original, and has the merit of going to the root of the difficulty. Dr. Lee, of Philadelphia, proposes that the United States buy up the island of Cuba and stamp out the yellow fever there.

DEATH OF DR. RUDOLF TAUSZKY.—Dr. Rudolf Tauszky, at one time a well-known physician of this city, died on September 21st, at Bloomingdale Asylum, where he had been a patient for over three years, having been confined there soon after making an attempt to kill his young wife and to commit suicide. Dr. Tauszky was about fifty-three years of age at the time of his death. Dr. Tauszky, who was born and educated for the medical profession at Pesth, Hungary, came to this country in 1862, was a hospital surgeon in Washington, and afterward served a little time in the field. He came to this city in 1868 and was successful in building up a practice. He served on the Board of Health for a time and became interested in the tenement-house problem, and lectured and wrote a great deal on sanitary reform. He was for nearly ten years connected with Mount Sinai Hospital. For some years before his retirement he was frequently called as an expert in cases of alleged insanity.

GONE OVER TO THE QUACKS.—It is stated in the daily papers that two physicians of Buffalo, formerly connected as teachers with the medical school of the Niagara University, have recently set medical ethics at defiance and gone into the business of advertising themselves as specialists. They have been dismissed from the Faculty.

AN ASYLUM BURNED.—The Idaho Insane Asylum was destroyed by fire on November 25th, and eight lives were lost.

AN ANGLO-AMERICAN VIENNA MEDICAL ASSOCIATION has been formed for the purpose of furnishing information to English speaking medical men coming to study in Vienna. The office will be at No. 12, Landesgerichts Strasse. Membership will be open to any British or American physician, or medical student, on payment of an entrance fee of one gulden.

THE EIGHTH CONGRESS OF RUSSIAN NATURALISTS AND PHYSICIANS will be held at St. Petersburg, from December 27, 1889, to January 7, 1890.

PROFESSOR BARDELEBEN.—A bronze bust of Professor Adolf Bardeleben, subscribed for by his pupils and friends on the occasion of his seventieth birthday, which he celebrated in March last, was unveiled on October 10th.

STERILIZED LINT.—M. Regnier renders lint sterile by heating it to a temperature of 120° C. (248° F.). M. Regnier has tested the antiseptic value of lint thus prepared in dressings applied after operations of various kinds with good results. At the recent Surgical Congress he stated that he considered sterilized lint equal to antiseptic dressings.

BY M. RICORD'S WILL a sum of ten thousand francs is given to the Académie de Médecine, and five thousand to the Surgical Society, to found prizes.

ORGANIZATION OF A STATE SOCIETY IN THE NEW STATE OF WASHINGTON.—In response to a call by the President of the Territorial Medical Society, there was a largely attended meeting of the profession at Tacoma, October 21st and 22d. The Territorial Society, as such, adjourned *sine die*. The formation of a State Society was then proceeded with, and the following officers were elected: *President*, Dr. Edward L. Smith, Seattle; *First-Vice-President*, Dr. J. S. Wintermute, Tacoma; *Second Vice-President*, Dr. M. Pietrzycki, Dayton; *Treasurer*, H. S. Willison, Port Townsend; *Secretary*, Dr. C. L. Flannigan, Olympia; *Board of Censors*, Drs. Shaver, Heg, Crump, Boswell, and Essig; *Board of Trustees*, Drs. Van Zandt, Van Buren, Merrick, Libby, and Marion. The regular standing committees were also appointed. There are about sixty-five charter members of the Society. The next meeting will be held at Spokane Falls on the second Wednesday in May, 1890.

A PROFESSOR OF HYGIENE AND PHYSICAL CULTURE has been endowed, in the sum of $25,000, at the Pennsylvania College at Gettysburg, by the parents of the late Dr. Charles H. Graff.

MEMORIAL TO THE LATE DR. CABELL.—The new chapel at the University of Virginia, in which the late Dr. James L. Cabell took such active interest, will contain a memorial window in his memory. Contributions for that purpose of not more than $3.00, by alumni of that institution, may be sent to Dr. William C. Dabney.

AN EFFORT is being made to start another Woman's Medical College in Cincinnati.

PROFESSOR S. B. HOWELL has resigned his chair in the faculty of the University of Pennsylvania. Edward D. Cope was elected to succeed him.

LIMITATION OF OFFSPRING.—A discussion is going on in the columns of *Kansas* the *Medical Journal* upon the subject of the "limitation of offspring." A correspondent ventures to deny the accuracy of Burns' "Cotter's Saturday Night," and says that, in point of fact, "at night the brood comes training home, each with a dozen questions to propound, and all begin at once, while she (the mother) with aching limbs and throbbing head, becomes bewildered and exclaims, 'Get out! Go away, you torments, you,' and no question gains attention." Burns finds a warm champion in the editor of the *Journal* however, who shows by statistics that the presence and possession of children prevents suicide and insanity. Arguments upon this subject are of little weight. No person with any moral sensibility or medical knowledge whatever would ever attempt to justify fœticide and abortion.

AN AMERICAN HOSPITAL IN PERSIA.—The corner-stone of an American hospital at Teheran was recently laid by the Minister of the United States to the Court of the Shah. The proposal to erect the hospital originated with Dr. W. W. Torrence, of Teheran, and funds have been obtained partly by donations raised in America and partly by subscriptions in Persia itself, many distinguished Persians having made generous contributions.

# Society Reports.

## SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

*Second Annual Meeting, held in Nashville, Tenn., November 12, 13, and 14, 1889.*

FIRST DAY, TUESDAY, NOVEMBER 12TH—MORNING SESSION.

THE Association convened in the Senate Chamber, and was called to order at 10 A.M. by the President, HUNTER MCGUIRE, M.D., of Richmond, Va. Prayer was offered by the REV. R. L. CAVE.

The report of the Committee of Arrangements was made through its chairman, J. R. Buist, M.D., of Nashville.

DR. R. B. MAURY, of Memphis, contributed a paper entitled

### REPORT OF GYNECOLOGICAL WORK, WITH ESPECIAL REFERENCE TO METHODS.

The paper presents a brief summary of the more important portion of his operative work during the past year. With four exceptions, all of the operations reported were done in a private hospital, built especially for the purpose and under his own control. The summary embraces 21 laparotomies for the removal of ovarian tumors, or of the uterine appendages, or for the relief of obscure disease within the abdomen; 2 laparotomies for ectopic gestation; 28 operations for laceration of the cervix; 14 perineal and vaginal prolapse operations; 5 rectoplasties; 4 anterior colporrhaphies.

Dr. Maury summarized the methods as follows:

1. An aseptic field of operation and an aseptic surgeon. 2. A small incision, in the case of inflammatory disease in the pelvis, just large enough to introduce, and work with, two fingers. 3. Aseptic silk ligatures, as fine as may be consistent with safety in tying. 4. Enucleation of diseased structures, in spite of firm adhesions and even profuse hemorrhage. 5. Irrigation by means of the siphon-trocar, as a substitute in most cases for sponging. Using simple hot water for this purpose and excluding all antiseptics. 6. Drainage often, and whenever one is in doubt as to its necessity. 7. Careful replacement by spreading out of the omentum before proceeding to close the wound. 8. Inclusion of all the structures in passing the abdominal wall sutures, and replacing the deep sutures half an inch apart. 9. The use of means for moving the bowels on the second or third day after removing the appendages, and the avoidance, if possible, of opium. Discussed by Drs Wathen, Price, Stone, Potter, and Johnstone.

DR. W. O. ROBERTS, of Louisville, Ky., read a paper on

### DIRECT HERNIOTOMY,

in which he reported ten cases, and did eleven operations. Seven cases occurred in females, three in males. Three were cases of umbilical hernia, three were femoral, three inguinal, and one ventral. Six of the operations were done during strangulation, while five were performed for troublesome, irreducible hernias. In the six cases of strangulated hernia the sexes were equally represented. Three were inguinal, two femoral, and one umbilical. In five of them the operation for radical cure was done. The remaining case was one of strangulated hernia where stercoraceous vomiting existed for eight hours before it was seen. General peritonitis was evident at the time of the operation. Much reddish stuff escaped when the contents of the sac were returned. Death followed in thirty-six hours. He had since thought that if, after returning the contents of the sac, he had done a low median laparotomy and washed out the peritoneal cavity, the result might have been different.

The four cases of irreducible hernia were all in females. Two were umbilical, one femoral, and one ventral. In one of the former a second operation was made necessary by the hernia recurring at the end of six months. The tumor also reformed, at the end of ninety days, in the case of femoral hernia. The remaining eight cases continue well to the present date.

In all the cases the sac was first cleanly dissected out, and not opened until all hemorrhage was entirely checked. Both in the ventral and umbilical hernias the integument and fascia were divided by an elliptical incision. After opening the sac all adherent omentum was tied with catgut and excised. The remaining contents were then returned into the cavity. In one case of umbilical hernia the neck of the sac was tied close to the margins of the opening, and cut away immediately in front of the ligature. The stump was then fastened tightly in the opening with silk-worm gut sutures, and the wound finally closed by interrupted sutures of the same material. In this case no suppuration occurred, but the hernia recurred at the end of six months. In both the other umbilical and in the ventral hernias the neck of the sac was excised on a level with the abdominal opening and sutured with catgut. The opening itself, after its edges were freshened, was closed with the continued suture of chromatized catgut in the ventral hernia and aseptic corded silk in the umbilical cases. The superficies were brought together by silk sutures, which were continued down to the aponeurosis.

In the femoral hernias he adopted the practice of Mitchell Banks. In the cases of direct inguinal hernia, after tying the neck of the sac just within the ring, and removing all in front of the ligature, the ring was closed with catgut sutures.

In the cases of oblique inguinal hernia he did Mr. Ball's operation, which consists in freeing the neck of the sac up to the internal opening, ligating it, cutting away all in front of the ligature, then twisting the neck upon itself to effect closure of the peritoneal orifice, and finally stitching the stump to the pillars of the ring to guard the neck against untwisting itself.

DR. VIRGIL O. HARDON, of Atlanta, Ga., read a paper entitled

### THE ABORTIVE TREATMENT OF ACUTE PELVIC INFLAMMATION.

He said the views held by gynecologists in regard to acute inflammation in the female pelvis have, within the past few years, undergone a radical change. The inflammatory processes formerly regarded as idiopathic, or at least as primary affections, are now almost universally recognized as dependent upon antecedent disease in the ovaries or Fallopian tubes, especially the latter. This change of opinion has to a large extent been due to the result of advances in surgery, which have enabled the conditions of the pelvic organs to be studied in the living subject by immediate inspection and palpation, instead of through the medium of the vaginal tissues; consequently it is even that a change of opinion on this subject has been most marked among those men who have had large experience in abdominal work. The diagnostic value of abdominal section, under such circumstances, is almost as great as that of post-mortem examination, and hence the opinion of the laparotomist is entitled to very great weight. As a result of this mode of observation, the conclusion cannot be avoided that acute pelvic inflammation is, at least in the majority of cases, associated with septic, gonorrhœal, tubercular, or some other form of inflammation of the tubes. There are two forms of inflammation which are recognized as occurring within the pelvis as a result of tubal disease—pelvic cellulitis and pelvic peritonitis. In many cases both forms of inflammation are simultaneously present in the same subject, and it is not improbable that in all cases when either is present, the other also exists in a greater or less degree.

It is hardly possible, when one considers the anatomical relations of the pelvic cellular tissue to the peritoneum, to

conceive of an inflammation of the one structure without a greater or less implication of the other. In the majority of cases one form of inflammation can be recognized as forming the preponderating element of the disease, to which the other plays only a secondary rôle.

The constitutional symptoms consist of acceleration of the pulse, elevation of temperature, severe pain in the pelvis extending down the thighs, tenderness of the hypogastric region and inguinal region, a sense of weight and fulness in the pelvis, difficult micturition, painful defecation. These symptoms are most marked in the acute stages, and are somewhat diminished as soon as solidification has taken place. They continue, however, with lessened intensity, into the third stage of the disease.

The treatment consists in the withdrawal of the effusions from the cellular tissue by means of the aspirator, etc. Where pus-tubes are present we would advocate their removal.

Dr. Joseph Price, of Philadelphia, said his experience was a little different from that of the essayist. Relief from salines and the aspirator in the cases reported may have been justifiable, but pus-tubes in every instance call for abdominal section. He then exhibited some pus-tubes, one of which was seven inches in length, and called attention to their frequency in cases of pelvic inflammation. He said, thirteen years ago a woman living in Pottsville was treated by a prominent gynecologist for pelvic peritonitis. Sponge-tents were used, and the patient made a doubtful recovery. Eight years ago Dr. Goodell effected drainage through several sinuses then existing, three or four being about the sacral region, two or three in the groins, and one in the anterior abdominal wall Six weeks ago Dr. Price evacuated two gallons of pus in the same patient. A perfect recovery was brought about in some of his cases only by abdominal section and the removal of pus-tubes. The history and symptoms in his cases were identically those mentioned by Dr. Hardon. In the light of our present accurate knowledge, acquired by a large experience in the pelvis, the conclusion is that the entire subject of pelvic peritonitis and cellulitis will have to be rewritten. The sharp distinctions between the one and the other are refinements that the surgeon no longer seeks. Peritonitis the result of tubal and ovarian disease is exceedingly common. Gonorrhœa is the most common cause of all.

Dr. George J. Engelmann, of St. Louis, said there was a fascination in the results achieved by Dr. Price and other operators, but he thought the pendulum was swinging too far in that direction. He could endorse the surgical treatment advocated by Dr. Price in dealing with cases of pelvic inflammation which result from salpingitis, or where there was pus in the tubes. Many of the cases which were formerly called pelvic cellulitis are the sequences of salpingitis or pus in the tubes, and he was satisfied there are cases which exist without salpingitis.

Dr. W. G. Ewing, of Nashville, said that when he began to practise he was on the conservative side, but is satisfied that many of the cases which came under his observation could have been dealt with surgically and successfully. He favored early operative interference, and said the surgeon should not delay in such cases, for by so doing additional adhesions were apt to form with extension of the inflammatory process.

Dr. Hardon, in closing the discussion, said he feared he had been misunderstood, but would now say that pus-tubes admitted of but one rational treatment, and that was their removal. He invariably recommends this to be done, but what should the surgeon do with those patients who will not permit an operation?

As regards pelvic cellulitis without disease of the tubes, he could corroborate the statements of Dr. Engelmann, and called attention to two cases he reported last year to the Association which verified the fact. In these cases he aspirated and withdrew several drachms of serum from the cellular tissue. Subsequent examination revealed absolutely no disease of the tubes. He has examined these patients from time to time, but not the slightest evidence of tubal disease could be found, and there has been no recurrence of the pelvic inflammation.

Dr. W. D. Haggard, of Nashville, read a paper on

THE IMPROVED CÆSAREAN SECTION VERSUS CRANIOTOMY,

in which he said that the improved Cæsarean section offers justifiable means of saving both mother and child, and relieves the heart and conscience from the charge of scientific murder. Embryotomy on a living child will soon cease to be regarded as a scientific, or even a justifiable, operation. This seems to be foreshadowed by the statistics of Caruso, who reports a case in detail by Sanger and one by Zweiffel, and adds statistics up to October, 1888, comprising 135 cases. Six successful cases were known in addition to Caruso, but the details necessary for publication were lacking. German operators have performed 74 of these operations, Americans 18, Australians 16, the results obtained by American surgeons being inferior to those of German and Australian operators. The results show a large per cent. of recoveries among mothers in all cases, and a still larger per cent. in the case of children. In three cases in which the operation was done a second time, both mothers and children recovered. A careful estimate of the results of craniotomy under antiseptic precautions shows that 23.04 per cent. of mothers recover. Selecting similar cases on which section was performed, the percentage of recoveries in these cases was 89.04 and 100 per cent. of children.

Dr. W. H. Wathen, of Louisville, read a paper on the

TREATMENT OF ECTOPIC PREGNANCY.

He said, in order to adopt the best treatment in ectopic pregnancy, it is necessary to know its correct pathology; failure in this particular has resulted in a variety of methods of treatment, and gynecologists of good ability differ widely in their views. But physicians who recognize that ectopic pregnancy is probably always tubal in its origin, are united in their opposition to the use of electricity or other means to destroy fœtal life. They prefer the removal of the gestation sac by laparotomy. He referred to the fact that Thomas adheres pretty much to the old classification of Parry and De Zeimeris, and that he speaks of an "impregnated ovum attaching itself primarily to the peritoneum, and of a fœtus and placenta entering the peritoneal cavity by rupture and developing there." He denied the possibility of an ovum attaching itself primarily to the peritoneum, and said that the placenta could not become separated from the tube and then become attached to other structures; the ovum must be held immovably in one position before its villi can penetrate the tissues; the placenta may become slowly separated from its tubal attachments, and fasten itself to other structures by making epiphytic inroads upon the abdominal walls or viscera by stripping off the peritoneum.

He did not believe that a classification based upon old statistics of post-mortem examinations could be correct, because these examinations were made by men not trained in pathological and microscopical research, who could not accurately distinguish the tissues, often matted together and entirely changed in physical appearance.

He divided the treatment of ectopic pregnancy as follows: 1. The treatment before primary rupture of the tube. 2. The treatment after rupture of the tube into the folds of the broad ligament, and before the period of fœtal viability. 3. The treatment where the sac ruptures into the peritoneal cavity. 4. The treatment after fœtal viability, and at the full period of gestation. 5. The treatment after death of the fœtus, at or before the full period of gestation.

He did not believe that a correct diagnosis is ever probable before primary rupture, and in no instance would he use electricity to destroy fœtal life. He preferred laparotomy, and claimed that the immediate and subsequent results would be better. He said, that while Dr. Harbert in 1849, Kiwisch in 1857, and Dr. Rodgers

in 1867, had suggested the removal of the sac in tubal rupture, he was probably the first to recommend its removal, if the diagnosis is made before rupture. If the tube has ruptured into the folds of the broad ligament, and pregnancy has continued four and a half or five months, he advised expectancy, and to operate after fœtal viability, but before the beginning of false labor. He advocated the removal of the placenta and fœtal membranes where it is possible to do so, and control hemorrhage by ligation *en masse* at the proximate end of the large vessels. If this cannot be done, it is best to leave the placenta to be absorbed and close the abdominal wound aseptically, after the fashion recently described by Mr. Tait.

---

AFTERNOON SESSION.

DR. W. H. WATHEN, of Louisville, read a paper entitled "The Treatment of Ectopic Pregnancy." This paper was followed by impromptu remarks on "Perineorrhaphy," by Dr. A. W. Johnstone, of Danville, Ky.

DR. JOSEPH PRICE, of Philadelphia, contributed a paper on

PUS IN THE PELVIS, AND HOW TO DEAL WITH IT.

By pus in the pelvis he meant pus that has its *fons et origo* in the pelvic organs or their investment. The rarer causes of pus in the pelvis may be said to be: 1, Carious bone, as psoas abscess; 2, traumatism, sloughing, results of electricity, direct violence, etc.; 3, foreign bodies, as extra-uterine bones, etc. The general rule is that pus in the pelvis is always the result of diseased conditions of the uterine appendages, whether it occurs as the result of a ruptured extra-uterine pregnancy, a suppurating ovarian or dermoid cyst, or salpingitis caused by gonorrhœa, parturition, dirty instruments, electricity, or what not. In general, then, when the surgeon finds pus in the pelvis, he will find its origin in the uterine appendages. He had seen pus discharging from the rectum, from the bladder, the umbilicus, and from the vagina. He had seen psoas abscess, perforating appendicitis, idiopathic peritonitis, and typhoid fever, and found the seat of trouble in the tubes and ovaries. In all his experience he had never seen pus in the pelvis independent of disease of the appendages. To make the statement definite, he had seen more than once double pyo-salpinx and double ovarian abscess contained in a pus-pocket in the peritoneal cavity, composed of adherent intestines and inflammatory tissue—four abscess cavities contained within a fifth. Again, he had seen a single pus-tube with four distinct pockets in it. Pus can burrow through the cellular tissue and find vent, as before stated. How shall pus in pelvis be treated? The general principles of surgery for the treatment of pus in any other part of the body apply with equal force to the pelvis, namely—where pus is present evacuate it; and secondly, remove the cause of the suppurative process. It is equally unsurgical and unscientific to allow pus to remain in the pelvis as it would be to allow it to remain in the brain, in the mammary gland, or under the fasciæ in any part of the body. It is equally unsurgical to allow a suppurating tube or ovary to remain in the pelvis as it would be to allow a sequestrum of dead bone, or to allow a necrotic placenta or membranes to remain in the uterus. These principles do not admit of evasion. All sorts and kinds of treatment have been tried without avail. Every man of experience knows the futility of counter-irritation, local depletions, or a general systemic treatment in the vast majority of cases.

There are only three methods of treatment common to physicians to-day, namely—electricity, vaginal drainage, and abdominal section with the removal of the diseased parts, thorough irrigation of the peritoneal cavity, and drainage.

The first of these methods need scarcely be mentioned in cases where pus is already present. Electricity has no place in the treatment of pus in the pelvis. Vaginal drainage is a crude, inefficient method, and is not so safe as some would have us believe. In abdominal section we have the quickest, easiest, most exact, and therefore safest, mode of treatment for pus in the pelvis. A small incision, rapid enucleation of the offending tubes and ovaries, the breaking up and evacuating of the separate pus-pockets, the separation of adhesions, the thorough washing out of the peritoneal cavity by copious irrigations of warm distilled water, the placing of a glass drainage-tube in the most depending portion of the peritoneal cavity, and the careful closure of the abdominal incision, gives the patient the quickest relief, permanent cure, and very often snatches her from an impending death. Moreover, here we attain the most ideal treatment, for at no other point of the body can we enucleate completely an abscess with its containing walls and pyogenic membrane. However, we should always bear in mind that the province of the surgeon is, first, to save life, then to relieve suffering, rather than to perform ideal operations. Many patients dying with pus in the pelvis need but a feather's weight to depress the beam. In such cases the indications are to evacuate the pus, wash out the cavity, and wait until a future time to remove the offending cause.

Discussed by Drs. Hardon, Engelmann, Stone, Robinson, Hadra, and Potter.

DR. W. L. ROBINSON, of Danville, Va., read a paper on

GYNECOLOGY IN ITS RELATION TO OBSTETRICS,

in which he spoke of the cervix uteri in its pathological condition, predisposing to hemorrhage prior to labor, laceration, and septic absorption. He could find no explanation in medical literature of the cause of ulceration of the cervix, non-specific and non-malignant, causing hemorrhage in two cases which came under his observation within the last twelve months. He used the word "non-specific" because of the perfect health of the patients prior to the pregnancy and since delivery—his knowledge and intimate acquaintance for years with husband and wife. The first case was seven months advanced, and she was spending the summer in the mountains for the benefit of the health of one of her children. She found herself unwell after a week, and the flow was sufficient to soil the clothing and require napkins. A physician was called who gave ergot and opium, which controlled it in twenty-four hours. Two weeks subsequently the conditions repeated themselves, and relief was obtained by the same remedies. She returned to the city and was again annoyed by a like hemorrhage, which came on about 7 P.M. daily in spite of the efforts of the attending physician to control it, which continued until the sixth day, the patient having reached home. Dr. Robinson was called and made an examination with speculum. He found the os granular, denuded of its mucous coat, and upon gently opening the os with uterine dilators he discovered a small clot adherent to the ulcer which caused bleeding when removed. He applied carbolic acid to the ulcer, and dusted the os and vagina with boric acid. He continued treatment until the parts were in a healthy condition, and delivered the woman at full term without hemorrhage, tear, or any unusual sequelæ. No placenta prævia existed, and not one drop of blood escaped after the first application of carbolic acid until after delivery, and then everything was normal. The second case occurred a few weeks subsequent to the first, with history and result similar.

He has for several years made it a practice to examine his regular patients whenever a yellowish or dirty-white vaginal discharge exists, especially if the vulva is irritated, and almost invariably finds the os granulated, whether lacerated or not, and he persistently treats them until restored to a healthy condition, explaining fully to the patient the importance of such treatment.

DR. BEDFORD BROWN, of Alexandria, Va., corroborated the statements of Dr. Robinson by the citation of a case. The patient had a bilateral laceration of the cervix. She became bitterly hostile to sexual intercourse with her husband, and had an intense dislike of his company and presence. This preyed upon her mind to such

an extent that she became insane. He treated the case with applications of nitrate of silver, and the lacerations healed perfectly. After that all symptoms entirely disappeared. The patient regained her reason, her affection for her husband, and had lost the hostility to sexual intercourse which she had. She has since borne three children. He has examined the condition of the cervix after each birth, and the repair is perfect.

The paper was further discussed by DR. RICHARD DOUGLAS, of Nashville.

### EVENING SESSION.

The Association met in Broad Street Museum Hall, at 8 P.M. The Address of Welcome was delivered by HON. A. J. CALDWELL, the response to which was made by DR. J. M. MATHEWS, of Louisville. DR. HUNTER MCGUIRE then delivered the Presidential Address, which was scholarly, timely, and well received.

### SECOND DAY, WEDNESDAY, NOVEMBER 13TH—MORNING SESSION.

DR. GEORGE J. ENGELMANN, of St. Louis, read a paper entitled

#### MENSTRUATION AND PREGNANCY AFTER REMOVAL OF BOTH OVARIES.

The following are the conclusions drawn from the history and microscopical examination of Dr. Engelmann's cases, which are corroborated by numerous cases of oöphorectomy and double ovariotomy now observed, whose histories have been recorded for a sufficient length of time after the operation:

1. That the continuance of menstruation after removal of both ovaries is due to remnants of ovarian stroma left *in situ*. 2. That portions of the ovarian tissue, however small, which remain after the removal of the greater portion of the organ, whether or not the Fallopian tube be preserved, may retain their activity and continue the functions of the entire organ. 3. Even elongated pedicles may contain ovarian stroma in which the functional activity of the organ may be continued. 4. That remnants of ovarian stroma do not necessarily preserve their vitality and functional activity.

The deductions of practical value to the operator are even of greater importance, and they are these: *a*. For the successful performance of oöphorectomy it is requisite that every particle of ovarian stroma shall be removed, if the desired result is to be expected with certainty. *b*. If shrinkage of fibres, the limitation of hemorrhage, or cessation of annoying symptoms is to be accomplished with the greatest certainty, both ovaries must be completely removed, and not even a particle of ovarian tissue left *in situ*. *c*. In the performance of double oöphorectomy in women not yet beyond the climacteric, and not suffering from utero-ovarian reflexes, such healthy ovarian tissue as may exist should be spared in order that function activity may not be impaired.

DR. W. D. HAGGARD, of Nashville, said it is very rare for a woman to menstruate regularly after removal of both ovaries and both tubes. He believed that the hemorrhagic discharges from the uterus after oöphorectomy depended upon some other cause than that of menstruation. It may depend upon some trouble connected with the endometrium, as suggested by Dr. Engelmann, a polypoid growth, or a congested condition of the blood-vessels which supply the endometrium. In January last he removed both ovaries and both tubes in a woman, and it is barely possible bits of ovarian stroma were left behind, as three months later the patient continued to have hemorrhagic discharges which greatly annoyed her.

DR. A. W. JOHNSTONE, of Danville, Ky., held that the ovary has no more to do with menstruation than the clitoris has. To prove this he had left ovarian tissue behind, yet menstruation had ceased. Dr. Johnstone gave at length his reason for this theory.

DR. VIRGIL O. HARDON, of Atlanta, Ga., had operated on a patient, about eighteen months since, for a bleeding fibroid tumor, removing both ovaries, and in removing the second ovary he feared he had not removed all the ovarian tissue, as the precarious condition of the patient would not permit a continuance of the operation. The patient recovered from the operation, and has menstruated with unvarying regularity from that time to the present.

DR. RICHARD DOUGLAS, of Nashville, said that Battey's operation of itself does not control menstruation, whereas in Professor Tait's operation, which consisted in the removal of both ovaries and both tubes, the gynecologist embraces in his ligature the nerve which controls menstruation.

DR. A. V. L. BROCKAW, of St. Louis, warmly took exception to the remarks of Dr. Johnstone, who was inclined to give Tait the credit of first performing oöphorectomy. He said he admired Tait's skill as an operator, but as a man he did not, for with characteristic modesty he (Tait) adds his name to operations that do not rightfully belong to him; as, for instance, the flap-splitting operation.

DR. W. H. WATHEN, of Louisville, said gynecologists were more familiar with the laws that govern menstruation in many respects than they formerly were, but that we still require more scientific investigation, personal observation, and experience to convince us that any one cause controls menstruation.

DR. A. W. JOHNSTONE arose to defend an absent friend. The statement made by Dr. Brockaw, that Tait was the originator of the flap-splitting operation is not true. A full description of the method could be found in a recent issue of Mundé's journal. It is true, however, that Tait has used it without knowing it had been described some twenty years ago by a Dublin surgeon, but he has given him due credit for the operation.

The paper was further discussed by Drs. G. Frank Lydston, of Chicago, Johnstone, and discussion closed by Dr. Engelmann.

DR. JOHN D. S. DAVIS, of Birmingham, Ala., then read a paper on

#### AN EXPERIMENTAL STUDY OF INTESTINAL ANASTOMOSIS,

in which he reported thirty-two adhesive experiments on dogs, and seventy-nine successful anastomotic operations, by means of his approximation catgut mats and catgut plates, for the purpose of illustrating the advantages of denuding the coaptation serous surfaces, and the integrity and absorbability of his catgut mats and plates.

He reported two applications of anastomosis to man. The first, ileo-colostomy, for obstruction in the region of the ileo-cæcal valve, by means of catgut mats; the second, jejuno-jejunostomy, for multiple gunshot injuries of the jejunum, with resection and lateral approximation, by means of catgut plates.

His paper was replete with suggestive advantages of anastomosis over circular enterorrhaphy, based on experimental facts. His anastomotic devices consist of catgut mats and catgut plates—oval and horseshoe. The mats are made of catgut in the following manner: A large continuous four-rib catgut frame is held in an oblong shape by four artery forceps, while the frame is being interwoven into an oval mat, of the desired size, by means of a small catgut thread armed with a needle. The coaptation threads are fixed by passing a needle and thread between the two middle ribs, and so returned as to loop two or three of the small gut sutures used in weaving the ribs together. The plates are made of any size, by means of an ordinary pocket knife, from a large one-eighth inch thick dry compressed plate of the uncut gut tissue—made for the author by William Snowden, of Philadelphia. The coaptation threads are fixed by passing them through the plates by means of a needle, or better, by means of an awl, and knotted to fix them. The horseshoe plates are made from the oval plates by cutting out one end of each of the oval plates. They are used for closing, in a hinge manner, extensive gunshot wounds of the convexity of the bowel.

His paper closed with the following propositions: 1. Approximation catgut mats may be made of any size in less than an hour. 2. Approximation catgut plates may be made of any size in from ten to fifteen minutes. 3. Approximation catgut horse-shoe plates are very valuable in intestinal repair from gunshot injuries of the convexity of the bowel. 4. Approximation catgut mats and plates absorb away in from forty-eight to sixty hours in gastro-enterostomy, and in from seventy to eighty hours in operations below the stomach. 5. Anastomosis by means of approximation catgut mats or plates furnishes the best conditions for the healing of the visceral wound. 6. Anastomosis can be performed by means of catgut mats or plates, without division of bowel, in five minutes; and with division or resection in fifteen minutes, including a continuous outside safety-silk suture around the circumference of the mats or plates. 7. Denuding the peritoneum of endothelium at the seat of coaptation hastens the exudation of plastic lymph, the formation of adhesions, and the definite healing of the intestinal wound. 8. When coaptation serous surfaces have been denuded of their endothelial covering by mechanical scraping, plastic adhesions readily take place, and definite healing—by the formation of a net-work of new blood-vessels in the product of tissue proliferation from the coaptation serous surfaces—is initiated in eighteen hours.

Dr. A. V. L. Brockaw, of St. Louis, Mo., followed with a paper entitled

INTESTINAL ANASTOMOTIC OPERATIONS WITH SEGMENTED RUBBER RINGS, WITH SOME PRACTICAL SUGGESTIONS AS TO THEIR USE IN OTHER SURGICAL PROCEDURES.

For many months the author has been experimenting with segmented rubber rings in all the anastomotic operations, and such operations as gastrostomy, cholecystotomy, duodeno-cholecystotomy, jejuno-cholecystotomy, and circular enterorrhaphy. The rings used by him are rapidly made, during an operation if necessary. All that is required is some rubber tubing or a soft ordinary rubber catheter and some catgut. He prefers tubing one-sixteenth to one-eighth of an inch in diameter. A section of this, of sufficient length to make a ring of the desired aperture, is cut into four to eight segments. Passing heavy strands of catgut through the lumen of these pieces, the ends are tied tightly enough to bring the ends of all segments together, forming an oval ring. To the catgut strands are tied from four to six silk apposition threads twelve to fourteen inches long, and the attachment of needles to these threads renders the ring ready for use. Another method is to pass a heavy double strand of catgut continuously through the segments several times, approximate the ends of the segments, and push the ends of the catgut into the tubing. This ring will have a better surgical finish, and after the apposition threads are tied between the segments the ring will maintain its perfect form until the catgut is absorbed. The rings were passed as early as the fifth day in one of his experiments. In forming an anastomosis, after ordinary No. 6 darning-needles are attached to the apposition threads, compress the ring and pass it through the opening made in the lumen of the bowel, then pass the threads through the intestinal wall from within outward. Ascertaining that the ring rests well in place, proceed to the second in the same manner; appose, and after scarification of the marginal serous surfaces, as suggested by Senn, tie the apposition threads. When possible, it is well to utilize omental grafts, which add to the security. With two such rings circular enterorrhaphy may be performed, the rings corresponding in size to the lumen of the bowel, care being taken that they are not so large as to press too much upon the delicate mucosa or to overstretch the bowel, as a local gangrene might then follow. Introducing a ring at each end of the gut at the point of section, the threads are passed through the wall less than one-third of an inch from the divided margins. The distal end of the gut is invaginated and the proximal gut pushed into the distal, bringing the serous surfaces in contact. The threads are then tied and a few Lembert sutures added, the entire operation requiring less than ten minutes. In one-half of his experiments with this operation the result was excellent. Of the fourteen dogs operated on by this method, in seven the results were all that could be desired; marked stenosis was found in several cases, and in all a ridge at the seat of the operation.

In a recent paper the essayist mentioned

A NEW PROCEDURE FOR CLOSING LARGE WOUNDS OF THE INTESTINE,

especially gunshot, whereby ordinary suturing stenosis would result. This method applies to wounds of the surface of the intestine; those of the mesenteric portion usually require resection. By this simple method wounds the size of a half-dollar may be closed in less than five minutes. The wound being trimmed and enlarged with scissors, a ring two and a half inches in diameter, made of eight segments of tubing, with six apposition threads, two on each side, so arranged that when the apposition threads are tied the ring is held bent evenly on itself. Such a ring is introduced into the bowel, the end apposition threads passed, then the lateral, using a single catgut suture in drawing the wound margins together at the point of flexure, in order to prevent eversion. A few Lembert sutures complete the operation. If two wounds are close together in the same loop, a lateral anastomosis might be formed, if possible. With more than two wounds close together, excision and lateral anastomosis will require less time than circular enterorrhaphy or the sewing up of several wounds. Other conditions where the single ring may be used are perforating ulcers, fistulas, etc. The great advantage of the segmented rubber rings over other devices used is the simplicity of their construction and the rapidity with which any number may be made. The large aperture of segmented rings makes it possible to perform ileo-colostomy by the following method, which the author believes is original: The ileum being divided a short distance from the cæcum, the divided end of the distal bowel is invaginated into itself, and secured by a continuous suture through the serous and muscular coats. Above the proximal end a clamp is placed, and a ring adjusted to the lumen; a slit is then made in the convex surface of the ascending colon and a ring introduced. The bleeding checked, the proximal end of the divided ileum is inserted into this slit, the threads tied, and Lembert sutures added. This operation may be quickly performed, and is indicated in such cases as irreducible intussusception of the ileum into the cæcum, and malignant diseases of the colon.

Appended is a series of operations with the results: Gastrostomy, 2 experiments, 2 recoveries; gastro-jejunostomy, 3 cases, 2 recoveries, 1 death from peritonitis;[1] jejuno-ileostomy, 1 case, result perfect; ileo-ileostomy, 2 cases, 1 death, due to perforative peritonitis; ileo-colostomy, 2 cases, 2 perfect results; colo-colostomy, 3 cases, 1 death; ileo-rectostomy, 2 cases, perfect results; circular enterorrhaphy, 14 cases, 7 deaths; duodeno-cholecystotomy, 3 cases, 2 deaths from peritonitis;[2] partial duodenectomy, 2 cases, 1 perfect result; partial jejunectomy, 2 cases, 2 perfect results; partial ileoectomy, 4 cases, 1 death; partial colectomy, 2 cases, 2 perfect results. *Summary:* Intestinal anastomotic operations, 14 cases, 3 deaths; circular enterorrhaphy, 14 cases, 2 deaths.

The single ring, formed of eight segments of tubing, was used in closing wounds varying in size from a quarter to half a dollar in 9 cases, with 1 death. The clamp devised by him and used in the operations is made of No. 12 copper wire covered with unperforated rubber tubing of small size.

Discussion postponed till afternoon.

(To be continued.)

[1] Dog tore one suture eight days after operation.

[2] This operation is difficult to perform on a dog for anatomical reasons.

# Correspondence.

## CONCERNING EXAMINATIONS FOR MEDICAL OFFICERS OF THE NAVY.

To the Editor of The Medical Record.

SIR: In the last number of THE RECORD, under the caption of "Vacancies Hard to Fill," there is an article which may cause some misunderstanding among possible candidates as to the character of the examination for admission to the Naval Medical Corps.

I refer to that part of the article in which the writer states that it is almost useless for any candidate who cannot show his A.B., as well as his M.D. degree, to present himself before this Board for examination; or words to that effect.

The naval branch of the Government service has never required candidates for appointment as assistant surgeon to show even their M.D. degree, being satisfied with its own examination as the test of professional acquirements; and, as a matter of fact, I assure you that of the last fifteen candidates found qualified by this Board, three only possessed degrees from literary colleges or institutions, while twelve were without any degree whatever other than doctor of medicine.

Very truly yours,

E. S. BOGERT,
*Med. Inspector U. S. Navy,*
*Pres. Exam. Board.*

NAVAL MEDICAL EXAMINATION BOARD,
U. S. NAVAL HOSPITAL,
BROOKLYN, November 19, 1889.

## THE ACTING ASSISTANT SURGEONS AND THE CONTRACT SYSTEM.

To the Editor of The Medical Record.

SIR: Your editorial in THE RECORD of November 2d attracted my attention. You have headed it with "The Hard Lot of the Acting Assistant Surgeon," and you present his case as one of severe hardship in a pecuniary point of view. In fact, it is the burden of your remarks. I fully agree with both the views of the "Association of Acting Assistant Surgeons U. S. A.," and yourself. They are not paid enough for their services. Yet there is no compulsion for giving their services for the recompense awarded. The fact is that a man, professional or otherwise, must have a living; if in the medical profession he must take his chances against competition with his fellows, or he must hire himself out for what he can get. The Government, like any individual, should get its work done as cheaply as possible. And evidently it has found that it can get all the service of the kind for the amount it proposes to pay I presume there are over twenty applicants for any vacancy or necessity that may arise. An experience as a contract or Acting Assistant Surgeon United States Army, a surgeon to a railroad company, and a manufacturing association, has taught me one fact, viz., that if I was not satisfied with the payment received I should decline to perform the service required; but those fifty Acting Assistant Surgeons decline to serve the Government for the price stipulated. There are another fifty ready to take their places. It is immaterial what is required of them. This they know beforehand, and if after making a trial they can, to use a vulgar expression, "get out," the fault is not in the contracting party of the first part. Certain duties are required for which so much money will be paid. The party of the second part is under no obligation to accept unless he is satisfied that he cannot do better with his property, viz., his accomplishments as a medical man. The remedy is easy—let him not make such a contract, and force the party of the first part to offer and give more for the service required. The fact is, there are too many doctors for the work to be done, and hence competition reduces the compensation. Government knows this as well as individuals, and finds it can get all the work required for the price offered. The contract surgeon has (if he chooses) an opportunity for outside work which adds to his wages, and oftentimes he can resign, and, by virtue of his previous position, enter upon a good practice in the neighborhood where he has been located.

From long observation the average doctor does not exceed $1,500 per annum, and were I to place it at $1,000 I would not be far out of the way. There is no obligation to become a "contract surgeon," and if after a trial of a month the wages are not satisfactory for the work performed, the remedy is easy. The same principle applies to all public offices: if the recompense is not sufficient or satisfactory, resignation is easy, and the vacancies can be readily filled. Whether private, public, or governmental, I am satisfied I can furnish the Government all the contract surgeons qualified for the duties required, to fill all the vacancies that may occur for insufficient compensation, and be glad for the opportunity.

Yours respectfully,

WILLIAM BRODIE, M.D.

DETROIT, MICH.

To the Editor of The Medical Record.

SIR: I have read with a great deal of interest the article which appeared in THE MEDICAL RECORD of November 2d entitled "The Hard Lot of the Acting Assistant Surgeon." I think it must have surprised the readers to know the humiliating position that educated, reputable physicians, who are over twenty eight years of age, are placed in, if they desire to enter the Medical Department of the United States Army. The only office open to a physician who is over twenty-eight years old, in the Medical Department of the United States Army, is that of an Acting Assistant Surgeon, United States Army, and the officer is paid less than a second lieutenant—the lowest commissioned officer of the army. It is almost incredible to believe that, if the Acting Assistant Surgeon is wounded and disabled in the service, while in discharge of his duty as a medical officer, and obtains a leave of absence for a short period on account of inability to perform his duty, that he loses his pay for the time he is absent, and that he is liable to be dismissed without trial or cause at the whim of his commanding officer, and that he has not the advantage given him of the civil service laws, which prevent employees of the Government from being removed without good and sufficient cause. This is certainly an injustice and discrimination against medical men who like army life, and are anxious to enter the service after they have passed the age of twenty eight years. Some of the Acting Assistant Surgeons of the United States Army have been in the service since the war, and are now too old or so accustomed to military life that they have no desire to commence the practice of medicine. I feel as confident as you do that the Acting Assistant Surgeon has the sympathy of the Surgeon-General of the United States Army, and also the medical staff, in his efforts to better his position and fix his status. The medical staff of the army is inadequately paid, and after the question of the Acting Assistant Surgeon, which is the most apparent injustice, is disposed of, the attention of the medical profession of the country might be called to it. From the *World Almanac* of 1889, page 175, I notice that the salary of the Surgeon-General of the United States Army is stated to be $4,500, while the salaries of other brigadier-generals are stated to be $5,500. The latter salary would be very meagre for the accomplished chief of the Medical Department of the United States Army. The petition of the Acting Assistant Surgeons of the United States Army appears to me to be very modest, and I cannot see how any lover of justice can object to it, and I believe as you do, that they ask for too little. During the late war of the Rebellion the Acting Assistant Surgeons of the United States Army wore the uniform and insignia of rank of first lieutenant, and performed the duties of Assistant Surgeons and Surgeons, and in several in-

stances had charge of United States General Hospitals when the pay was very small and the responsibility very great. The number of medical men who served in this capacity, and who patriotically gave their services to their country in its hour of need during the late war of the Rebellion was 5,532, and I understand that there will be an effort made at the coming Congress to commission and muster them in from the date of entry into the service, and muster them out or discharge them like commissioned officers at the date of the honorable termination of their service.

THE MEDICAL RECORD deserves commendation for calling the attention of the medical profession to the position their medical brethren—the Acting Assistant Surgeons—are placed in, and I think it is our duty, and I sincerely hope we will be able, to aid them in their efforts to obtain a living salary and the standing in the army that they modestly seek. The Acting Assistant Surgeon of the United States Army who is now in the service is so situated that he can be of little service in bettering his position. He can only make a statement that will call the attention of his medical brethren to the position he is placed in, to obtain their sympathy and support, which I feel confident will be cheerfully given. The article in THE MEDICAL RECORD on the "Hard Lot of the Acting Assistant Surgeon," I think, has voiced the opinion of the medical profession on their petition, and I take the liberty of informing you that it gave me great pleasure to read the editorial which called attention to the position that this class of very deserving medical officers are placed in.

Very respectfully yours,

JOHN T. NAGLE, M.D.

47 EAST TWENTY-FIRST STREET, NEW YORK.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 18 to November 23, 1889.*

LORING, LEONARD Y., Major and Surgeon. By direction of the Secretary of War the extension of leave of absence on Surgeon's certificate of disability granted in S. O. 241, October 16, 1889, from this office, is still further extended one month on Surgeon's certificate of disability. Par. 3, S. O. 268, Headquarters of the Army, A. G. O., November 16, 1889.

MOSELEY, EDWARD B., Captain and Assistant Surgeon. Relieved from duty at Whipple Barracks, Ariz., to take effect upon the expiration of his present leave of absence, and will report in person to the commanding officer, Fort Clark, Tex., for duty at that station, reporting by letter to the commanding general, Department of Texas. Par. 4, S. O. 268, A. G. O., November 16, 1889.

FISHER, WALTER W. R., Captain and Assistant Surgeon. Relieved from duty at the Presidio of San Francisco, Cal., and will report in person to the commanding officer, Fort Assiniboin, Mont., for duty at that station, reporting by letter to the commanding general, Department of Dakota. Par. 4, S. O. 268, Headquarters of the Army, A. G. O., November 16, 1889.

EBERT, RUDOLPH G., Captain and Assistant Surgeon. The leave of absence on Surgeon's certificate of disability granted in S. O. 109, May 11, 1889, from this office, is extended six months on Surgeon's certificate of disability. Par. 13, S. O. 270, Headquarters of the Army, A. G. O, November 19, 1889.

---

*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 23, 1889.*

RUSH, W. H., Passed Assistant Surgeon. Ordered to U. S. S. Saratoga.

URIC, J. F., Assistant Surgeon. Detached from the Coast Survey Steamer Gedney and ordered to the U. S. S. New Hampshire.

BRYANT, P. H., Assistant Surgeon. Detached from the Norfolk Hospital and ordered to the Coast Survey Steamer Gedney.

SMITH, GEORGE T., Assistant Surgeon. Detached from the Army and Navy Hospital, Hot Springs, Ark., and ordered to the Naval Hospital, Norfolk, Va.

STONE, E. P., Assistant Surgeon. After examination for promotion, await orders at Boston, Mass.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 23, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 32 | 10 |
| Scarlet fever | 43 | 5 |
| Cerebro-spinal meningitis | 1 | 1 |
| Measles | 35 | 6 |
| Diphtheria | 87 | 14 |
| Small-pox | 0 | 0 |
| Variola | 3 | 0 |
| Cholera | 0 | 0 |

CIRCULAR FOR THE INFORMATION OF PERSONS DESIRING TO ENTER THE MEDICAL CORPS OF THE U. S. NAVY.—The following circular, from the Honorable Secretary of the United States Navy, is published for the information of all concerned:

A candidate for examination and appointment in the Medical Corps of the Navy must be between twenty-one and twenty-six years of age, and must apply to the Honorable Secretary of the Navy for permission to appear before the Naval Medical Examining Board.

The application must be in the handwriting of the applicant, stating age and place of birth, also the place and State of which he is a permanent resident; and must be accompanied by letters or certificates from persons of repute, testifying, from personal knowledge, to his good habits and moral character, and that he is a citizen of the United States.

*Form of Application.*

———,

———, 1889.

TO THE HONORABLE SECRETARY OF THE NAVY,
*Navy Department, Washington, D. C.:*

SIR: I request permission to be examined for an appointment as Assistant Surgeon in the United States Navy.

I was born at — , and was —— years of age on the —— day of ——, 18—, and am a citizen of the United States, residing in ——, county of ——, in the State of ——.

I enclose herewith certificates as to moral character, habits, and citizenship.

Very respectfully,

——— ———

If, in reply to the above, the candidate receive a permit, he will notify the President of the Board of the fact, and request him to appoint a time for his examination.

Candidates will be expected to present to the Board testimonials of education and professional fitness.

The Board is required, under oath, to report on the physical, mental, moral, and professional qualifications of the candidate; so that the examinations are necessarily rigid and comprehensive, though simple and practical, and not beyond the attainments of any well-educated physician.

A successful candidate, upon the completion of his examination, will be notified by the President of the Board that he has been found qualified.

An applicant found "not qualified" may be allowed a second examination after one year, but not a third.

No allowance will be made for the expenses of persons undergoing examination, which, if uninterrupted, is usually completed within a week.

Appointments will be made as vacancies occur, and in the order of merit reported by the Board, but a qualified candidate, not appointed within the year, must be re-examined.

The officers of the Medical Staff of the Navy are as follows: Medical Directors, Medical Inspectors, Surgeons, Passed Assistant Surgeons, and Assistant Surgeons.

Vacancies in these grades (by death, or retirement at the age of sixty-two years) are filled in the order of seniority, and for each step of promotion a physical and professional examination is required by law.

The pay of an Assistant Surgeon in the Navy is $1,000 per annum "on leave or waiting orders," $1,400 "on shore duty," $1,700 "at sea," and, when at sea, one ration at thirty cents per diem in addition.

Eight cents a mile is the allowance when travelling under orders.

*Order of Examination:*—1. Physical. 2. Written. 3. Oral. 4. Clinical. 5. Practical.

*The Physical Examination* will be very thorough, and the candidate will be required to certify, under oath, that he is free from any mental, physical, or constitutional defects, hereditary taint, or disability of any kind that would be liable to interfere with the efficient performance of duty.

*Written Examination.*—The candidate will be required to address a letter to the Board of Examiners, stating concisely—

1. The date and place of his birth; the school, institution, or college at which he received his general education; the several branches studied, including his knowledge of general literature, and of the ancient and modern languages; the exact title of the medical school or schools at which he received instruction, and, *if an Alumnus*, the date of his graduation; the name and place of residence of his preceptor, and the time when he commenced the study of medicine; also, the title of the text-books studied or read on Chemistry, Anatomy, Physiology, Histology. Materia Medica, Pharmacy, Therapeutics, Theory and Practice of Medicine, Principles and Practice of Surgery, Minor Surgery or Mechanical Therapeutics, Medical Jurisprudence, Toxicology, Obstetrics, Hygiene, Biology, and Physics.

2. The opportunities he has had of engaging in the practice of medicine, surgery, and obstetrics, or of receiving clinical instruction; or whether he has or has not been a resident physician or interne in a civil or military hospital.

3. The number of subjects or parts of subjects he has dissected; what opportunity he has had to become familiar with minor surgery and bandaging, chemical and pharmaceutical manipulations, and the physical properties of drugs.

The candidate will append to this letter his name in full, post-office address, and his local address at the date of the examination.

*A Thesis or Short Essay* must next be written (without reference to notes or books) upon some professional or scientific subject indicated by the Board.

Written answers will then be required to twelve or more questions, propounded by the Board, on the following subjects:

Anatomy, Histology, Physiology, Surgery, Theory and Practice of Medicine, Obstetrics, Materia Medica, Chemistry, Hygiene, Medical Jurisprudence, Toxicology, and Physics.

*Oral Examination.*—The candidate will be examined orally upon his literary and scientific acquirements, including general history, natural science, and English literature, and professionally upon Anatomy (general, special, and surgical), Histology, Physiology, Theory and Practice of Medicine, Principles and Practice of Surgery, Chemistry, Legal Medicine, Toxicology, Materia Medica, Therapeutics, Pharmacy, Obstetrics and Diseases of Women and Children, Hygiene, Microscopy, and Physics.

Candidates possessing special knowledge of the higher Mathematics, Astronomy, Geology, Botany, Zoology, Literature, Art, and Ancient and Modern Languages, will be given full credit for their proficiency.

*The Clinical Examination of Patients* will be made by the candidate at a Naval Hospital, and will include the use of the Microscope, Thermometer, Laryngoscope, Ophthalmoscope, and other aids to physical diagnosis; after which he will be required to submit a written clinical report on one or more medical or surgical cases.

*The Practical Examination* will comprise surgical operation on the cadaver, the application of splints, bandages, and surgical dressings, the use of the microscope (for clinical purposes, and the recognition of pathological or other specimens), and chemical and pharmaceutical manipulations.

A candidate may withdraw at any period of the examination, with the consent of the Board, and may at a future time present himself for re-examination.

The Board may conclude the examination—written, oral, or practical—at any time, and may deviate from this general plan in such manner as it may deem best to insure the interests of the naval service.

Dr. Morse K. Taylor died at his home in San Antonio, Tex., on October 20th, after an illness of about two weeks. Dr. Taylor was born in Watertown, N. Y., but was taken to Michigan by his parents while still a child. He served in one of the Michigan regiments during the Mexican war, and at the close of that war began the study of medicine at Ann Arbor, where he graduated in the second class that left the medical department. After practising for a while in Illinois, he entered the Union Army as surgeon, and served in that capacity during the entire Civil War. He then practised in Iowa, but soon re entered the army, serving in the medical corps until retired on account of age. He then made his home in San Antonio, living with his son, Dr. F. M. Taylor. He had made a special study for some years of the climate of Texas, and at the time of his death had nearly completed a work on the climatology of this State, which is said by those who have seen portions of the manuscript to be of remarkable scope and detail. Dr. Taylor also wrote the article on the climate of Texas in the seventh volume of Wood's "Reference Handbook." His death was due to prostatic disease.

A Five Years' Course of Study for English Medical Students.—The Committee of Management of the Royal Colleges of Physicians and Surgeons of England have recommended an extension of the period of professional study to five years for candidates of qualification by the Conjoint Examining Board in England, and their recommendation has been accepted by the Council of the Royal College of Surgeons; while the Fellows of the Royal College of Physicians have referred the matter to the Council for further consideration.

The Hygiene of Russian Workshops.—At the Congress of Hygiene, held recently in Paris, Dr. Kacheva, a female physician, drew a most astounding picture of the horrors of the sleeping accommodation provided for workmen in Russian factories, which she characterized as exceeding those of steerage passengers in old emigrant ships.

A Medical Senator.—Dr. Francisco Alonso Rubio, some time physician to the Queen of Spain, and the leading obstetrician and gynecologist of the Peninsula, has recently been named a life senator by the Spanish Government. The appointment has given great satisfaction to the medical profession in Spain.

### ON VITAL AND MEDICAL STATISTICS.[1]

BY JOHN S. BILLINGS, M.D.,
UNITED STATES ARMY.

LECTURE II.

THE term "expectation of life" is used by different writers in different senses, and hence has often given rise to confusion and misunderstanding. It should be used only in the sense of the mean after-lifetime, that is, the average number of years which persons at any given age, in a given place, may expect to live. In a stationary population, where there is no migration, and where the births are exactly equal in number to the deaths, the expectation of life at any age would be found by dividing the sum of the number of years which the whole population lived after that age by the number actually living at that age.

*Table showing Expectation of Life.*

| | | Ages. | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | 0 | 5 | 10 | 15 | 25 | 40 | 60 |
| American Life Insurance Companies. | Males .. | .... | .... | 49.9 | 46.6 | 39.5 | 28.5 | 14.5 |
| Massachusetts, 1883-87 | Males .. | 39.7 | 52.7 | 49.3 | 45.1 | 38.2 | 28.2 | 15.3 |
| Boston, 1883-87 | Persons. | 33.3 | 47.2 | 47.5 | 44.7 | 37.1 | 28.5 | 16.7 |
| Providence, 1883-87 | Persons. | 40.8 | 51.1 | 48.3 | 44.2 | 37.5 | 27.7 | 15.0 |
| New York, 1879-81 | Males .. | 33.3 | 48.0 | 44.9 | 40.6 | 33 2 | 23.9 | 13.0 |
| Baltimore, 1880, colored | Males .. | 21.0 | 41.8 | 46.0 | 36.8 | 31.0 | 21 7 | 11.3 |
| Society of Friends, Philadelphia | Persons. | 43.7 | 51.8 | 48.8 | 44.6 | 37.5 | 28.5 | 15.6 |
| Society of Friends, England | Males .. | 45.3 | 53.8 | 50.5 | 46.4 | 39 9 | 29.2 | 14.4 |
| Benedictine Monks, Paris | ..... | .... | ... | ... | .... | 14.6 | 24.0 | 11.7 |
| English Life Insurance | ..... | .... | 50.6 | 45.6 | 40.6 | 34.0 | 24.5 | 12.6 |
| Dublin, 1841 | Males .. | 23.8 | 38.5 | 17.2 | 33.4 | 27.0 | 19.8 | 11.0 |
| Berlin | Males .. | 17.2 | 44.5 | 43.1 | 39.5 | 32.0 | 22.0 | 10.0 |

The term "expectation of life" is often confused with the "probable duration of life," which is the age at which a certain number of new-born children will be reduced one-half; so that for any one of these children it is an equal chance as to whether it will die before or after that age. The difference between the probable duration of life and the expectation of life may be understood from the following example: Suppose that of 100 children born, 30 live one year, 20 live five years, 30 live forty years, and 20 live sixty years. Then the probable duration of life is five years, because at the end of five years just one-half of these children will be dead, so that at the beginning it is an even chance for any one child as to whether it will die before or after the age of five years; but the expectation of life of any one of these children is 25.3 years, because these 100 children will in all live 25,300 years of life. In like manner, if ten of these children were to die at the end of every five years, the probable duration of life would be 25 years, and the expectation of life would be 27.5.

Another phrase sometimes used in vital statistics is "specific intensity of life." This is the quotient of the dividend of the number of persons living at any age by the number dying at that age, that is, $\frac{Px}{Dx}$, being the reverse of the ordinary mortality ratio.

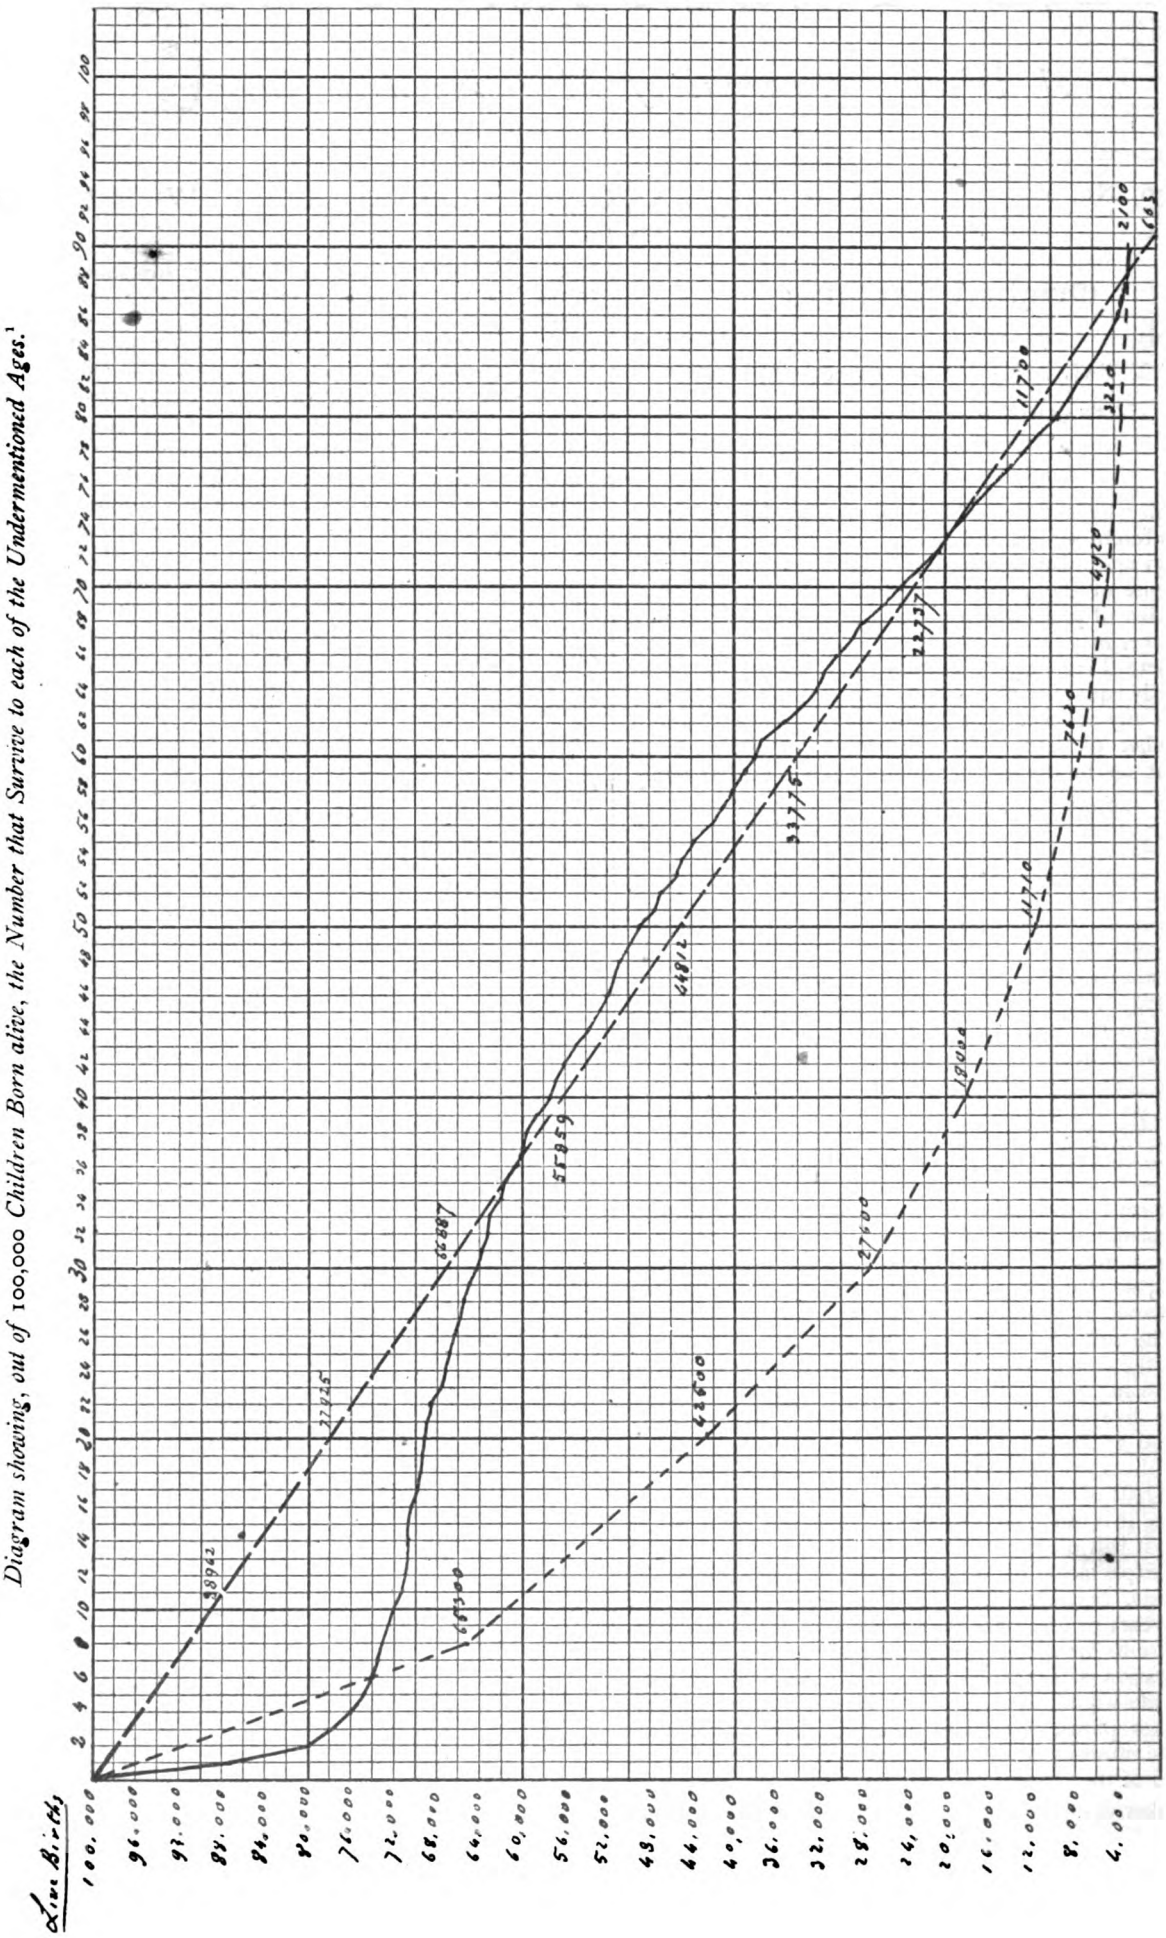
The chief source of error in an approximate life-table constructed directly from the census figures and a registration of deaths, without correction or adjustment, is due to the fact that there is a very considerable error in the number given of the living population in the first six or seven years of life. Usually the census figures show that the number of children two years old is greater than the number one year old, and that the number four years old is greater than the number two years old, owing to a tendency to erroneously report a child at these ages as being older than it is. If we undertake to adjust or correct these figures so as to truly represent the number living at each year, we usually have to make some assumptions as to the law governing the mortality, or as to what is sometimes called the law of life. This expression, the law of life, refers to the hypothesis that variations in mortality at successive ages take place in a regular succession which may be geometrically represented by a curve, and that therefore, if we know the mortality at certain ages in a given community, we can, if we know this curve, and if the number of observations were sufficient, deduce the mortality at other ages. Numerous formulas have been proposed for this purpose, from that of De Moivre in 1727, which is $Y = 86 - x$, $x$ being the age, and Y the corresponding number of the living, to the latest and most generally accepted formula of Gompertz, as modified by Mr. Makeham. This last is based on the assumption that a person's power of resisting death decreases as his years increase, so that at the end of infinitely small periods of time he loses infinitely small portions of his remaining power to resist destruction, death being considered as the consequence of two generally existing causes, the one a progressive, necessary deterioration, the other chance. If, for instance, there were a number of diseases to which young and old were equally liable and which were equally destructive at any age, the number of deaths among the young and the old by such diseases would evidently be in the proportion of the number of the young to that of the old. If there were no other causes of death but these diseases, the number of living and dying would decrease in a geometrical progression as the age increases. But if the liability to death is constantly increasing in a given ratio as the man grows older, then the number of the living will decrease in a greater ratio than a geometrical progression would indicate.

The diagram before you shows the diminution of vital force with advancing age as shown by De Moivre's hypothesis, by the geometrical progression formula, and by the English life-table.

This line of human life, which in some respects is not unlike the line in the palm of the human hand which the ancient teachers of chiroscopy also called the line of life, is that of the healthy and normal individual. Many persons do not at any time possess the amount of vital force which it represents; many infants at birth have but the capacity for a few hours or a few days of existence. Some men begin to grow old at forty; the atheromatous degeneration invades their arteries, the heart becomes fatty, and at fifty they are in extreme old age as regards the processes of retrograde metamorphosis, and the ability to resist death. Calculations and corrections based on such formulæ as these give interesting results, and are useful to life-insurance work, but they are unnecessary to the purposes of the sanitary statistician. Even the fundamental hypothesis upon which Gompertz' law is based, that the proportion of deaths at a given age is constant, is always untrue for any given age, as the prevalence of infectious and contagious diseases of various kinds, and

[1] The Cartwright Lectures, delivered before the Alumni Association of the College of Physicians of New York, November, 1889.

*Diagram showing, out of* 100,000 *Children Born alive, the Number that Survive to each of the Undermentioned Ages.*[1]



[1] See A. Newsholme, The Elements of Vital Statistics, p. 237. London, 1889. —— Dr. Ogle's line (English life table), 1871–80; — — — Dr. Moivre's line, May 1, 1886; - - - - Geometrical progression line.

of various lethality, varies with different years, and for this reason it is desirable to have the records of deaths for a considerable period of time—at least three years, and, better, ten to twenty years, in order to correct these variations.

It is impossible to calculate a life-table for the United States as a whole, since we have no accurate information as to the total number of deaths occurring in any given period of time in the United States, and still less as to the number of deaths occurring at each group of ages. But even if such table could be prepared, it would be of very little interest or use, since the conditions of the various sections of the country as to climate, occupations, prevailing diseases, character of inhabitants, etc., are so widely diverse that the average or mean would scarcely be applicable anywhere. The most useful life-tables for sanitary purposes are those which relate to certain circumscribed localities, such as a single city, or even a single ward of a city; but for scientific and medical purposes, the most useful are those which relate to particular classes of people, particular occupations, etc. There is a special difficulty in preparing an accurate life-table for a city, due to the effect of migration into and out of the city, from and to the surrounding country, which disturbs very much the rates of death at different ages. The mortality in a great city is almost always reported as less than that which the actually existing causes of death and disease tend to produce, because domestic servants, shop-girls, and others, who have come from the country, go back to their rural homes when their health begins to fail after a year or two of city life, and there die. This is especially the case in regard to deaths from consumption and diseases of that class. The groups of ages which are thus specially affected are those between fifteen and twenty-five years, and therefore the mortality at this group of ages in the large cities, as calculated from the number of deaths, is too small to properly represent the causes of death acting on the population at those ages. On the other hand, the mortality at the same ages in the rural districts near the city will be correspondingly unduly increased.

The data necessary for the construction of life-tables are comparatively rarely available for the purposes of the sanitarian. Hence, while admitting that these furnish the only true measure of public health, registrars of vital statistics and sanitarians have sought for other standards for such measurement, the data for which could be more readily obtained and more easily applied. Especially has the search been made for some means of measuring sanitary conditions and progress from the data furnished by deaths alone without reference to population. One of the most common of these is the use of the period of infancy from 0 to 5 years, by comparing the number of deaths at this period with the total number of deaths. It is very certain that the period of infancy gives the most sensitive test of sanitary conditions, but the comparison must be made, not with the total number of deaths at all ages, but with the number of the living population furnishing such deaths.

In Europe it is more common to confine the calculation to children under one year of age, and these are much more valuable there than they would be in this country because they have there a much more complete registration of births, and therefore the relation between the number of infants born and dying within the first year of life can be ascertained with an exactness which is quite out of the question in this country.

Another method, which we can only use for a census year, is the use of the ratio which exists between the total number of births during the year and the number dying during the year out of this number of births. This is not the same as taking the total number of those dying under one year of age. For example, in the city of Brooklyn, during the last census year, there were 8,805 births, and of these 1,408 died—leaving, on the date of the census, 7,397 living children under one year of age, putting aside the effects of migration; but the total number of deaths of white male children under one year of age in Brooklyn was 2,059—hence 159.9 per 1,000 of those born within the year died within the year, while the deaths of children under one year were 278.4 per 1,000 living at the end of the year, with a still higher rate for the year.

The test of sanitary condition which is most generally employed in this country is the proportion of the number of deaths which occur in children under five years of age to the whole number of deaths reported. This does fairly well in comparing the rates of the same city, in which it may be presumed that the general ratio of age-distribution is nearly uniform at different times, but it is a very fallacious method of comparing rates of different cities or localities. For example, during the last census year the ratio of deaths under five years per 1,000 of total deaths was in Alabama 475.9 for males—in California, 250.0; but in Alabama the proportion of male children under five years to the total population is 17.5 per cent., while in California it is only 9.1, or but little over half the Alabama ratio, and hence the true rate is actually higher in California than it is in Alabama, although the figures would indicate the reverse.

Much the same may be said of comparison of deaths at a given age-group to total number of deaths, which is apt to give very misleading conclusions. For example, suppose, in a given city, the total number of deaths of children under five years of age were thirty per cent. of the total deaths, while in a given class of people in the same city they were only ten per cent. of the total deaths; it would be by no means safe to infer that this special class was in a better sanitary condition, because among the poorer classes the proportion of children is always relatively large, which implies a large population exposed to these special diseases, and consequently a larger number of deaths under five years of age, without reference to the sanitary condition.

Another test which has been proposed is that of the mean age at death, which is the quotient of the sum of the ages of different individuals at death, divided by the total number of deaths. This is only useful in comparing the conditions of two populations when the age and sex constitutions of these populations is the same. It is out of the question to apply the test to different occupations; as, for example, to compare the mean age at death of major-generals with that of second lieutenants. The chief use of this test is in its application to different causes of death, but even for this purpose the death-rate in relation to population is much better.

A considerable part of the errors to which one is liable in comparing the mean age of different occupations at death may be avoided by excluding from the computation all deaths of children under five years of age.

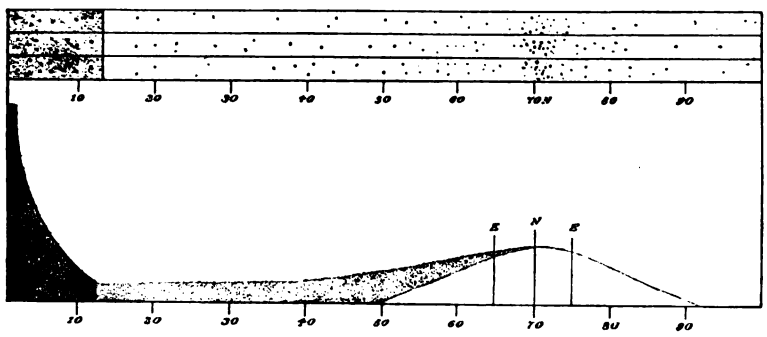
Although the expectation of life, or mean after-lifetime, is the standard of comparison almost universally accepted by statisticians, it is, in some respects, not a very satisfactory one, since it is often misunderstood by the public, which is apt to use the word "mean" in the sense of usual or ordinary, that which occurs most frequently. But the ordinary lifetime, or, as Bertillon calls it, the *vie normale*,[1] is a very different matter, as will be seen from the diagram on next page.

This indicates that after the perils of childhood are passed the greatest number of deaths cluster about the age-period of seventy years, and the popular phrase here would be that it was a premature death which occurred in a man under sixty years of age.

The great majority of the mortality statistics prior to the present century are necessarily incorrect and unreliable, because they are based, for the most part, on the data of deaths alone. The deaths can only be taken as a measure of probable duration of life for any community when the births and deaths are equal and there is no migration, a state of matters which must very rarely happen and be of very brief existence.

[1] Bertillon, M. Jacques: Sur la Vie moyenne et la Vie normale, Bull. de la Soc. d'Anthropologie, Paris, 1879, 3e Sér., Pl. op. p. 470.

Among the many expedients which used to be employed for estimating population was that of multiplying the number of living in which one death was supposed to occur, by the number of deaths. That is to say, by guessing at a factor which could only be ascertained by comparing the annual deaths with the number living. Take, for example, the estimates of the population in London made by Graunt in 1662 on the basis of one death occurring out of every 32 living, which made the population to be 403,000. In 1683 Petty, taking the mortality to be 1 to 30 persons living, made the population to be 669,930.



One peculiar thing about this method is, that it is liable to make the population seem the largest at those periods when it was in reality the smallest; for when the number of deaths was unusually large by reason of an epidemic, which would actually lessen the number living, it would show an apparent increase in the population for the same period.

It may, perhaps, be asked why it is, if the nature of the data which are required to make mortality statistics reliable and satisfactory is so well known, that more of them are not provided by the municipal and State Officers charged with the registration of vital statistics. For example, New York City has a very perfect system of registration of deaths, which is in competent hands and is well executed. Why, then, has New York City published no separate mortality report since 1883, and why, in the reports which it has published, does it not give the data with minuteness of grouping so that we might know the number of deaths at each age, of each sex, and of each race and occupation in each ward from each cause of death, instead of giving, as it gave in its last report, the number of deaths from each of certain causes of death for each of a few groups of ages, and separately for each sex, and for natives of the United States, natives of foreign countries, and colored; to which is added a statement of the deaths from zymotic diseases in each ward?

In order to understand the answer to this, it is necessary to have a clear conception of the difference in cost of tabulation and publication according to the mode of grouping of the data. If, for example, the deaths are given by twenty groups of ages and by sex and by color for each of the 24 wards, and for the city as a whole. it will require 49 columns to do this. If we make the distinction for, say, 100 different causes of death, allowing fifty lines to the page horizontally, and twenty columns vertically, giving 1,000 places per page, we should get all this information for the city on four pages; but if we wish to show the number of cases of death from each cause at each group of ages, of each sex and each color in each ward, we shall have to have 2,000 columns, which will make about 200 pages. If it be desired to estimate the influence of seasons in connection with all these things, we must have a similar table for each month, or 2,400 pages large octavo.

Again, let us suppose that we wish to have the data fully presented in order to estimate the influence of occupation upon health. We will only ask for details of one hundred occupations in males. But we should like to know the number of deaths in each of these occupations for each of, say, ten groups of ages, in each of at least five races, in the married and single, in each of twelve months, for each of the twenty-four wards, for each of, say, 100 different causes of death, giving 288,000,000 possible places, making 288,000 pages large octavo.

It is, of course, out of the question to present the data in any such detail as this, and it is therefore necessary to make a selection of combinations which will indicate the most interesting relations of the several points under discussion.

It is, however, often very difficult, and even impossible, to tell precisely what combinations it will be necessary to make to get at the probable explanation of an especially high or low death-rate in a given group; and hence we sometimes have to make a very considerable number of tentative combinations and tabulations, from which we may select only a few as really throwing light on the matter, and therefore as worth publication.

When we have to tabulate data in such a way that the individual items are to be distributed through a thousand columns or more, and each of these to be summed up for different localities, a vast amount of clerical labor is required. For distributing in 1,000 spaces the various items assigned in each death-certificate, if it be done by the old-fashioned system of tallying on a large sheet, an expert clerk will not be able to tally off more than 1,000 records of death per day; so that for, say, 30,000 deaths, which is less than the average number of annual deaths in New York City for the last ten years, it would require the labor of a clerk 30 days to produce a single page table, about one per cent. of what is needed.

By the use of cards or slips, tallying machines, adding machines, and sorting boxes of various kinds, this labor may be much reduced. One of the latest methods of doing this is by the use of cards of a uniform size, in which holes punched in certain parts of the card correspond to the various divisions of locality, time of death, sex, age, occupation, cause of death, marital condition, etc. These cards may then be passed through a machine which registers on a series of dials such combinations of the data as the dials may be adjusted for, by means of electrical connections established between a metal plate below and a series of metal rods above, wherever there is a hole in the card.

Death-rates, even when derived from complete and accurate data and compiled in the most satisfactory manner in the form of life-tables, necessarily give only an imperfect view of the prevalence of disease in a community, or of the relative amount of disability among the people, requiring extra labor by the productive class due to the recurrence of sickness. Many forms of disease which render life more or less of a burden, and some of which totally disable the individual from earning his subsistence, seldom or never appear in the registers as a cause of death; while even of those diseases which are reported as causes of a considerable proportion of deaths, we can rarely at present indicate any definite or certain relation between the number of cases of the disease and the number of deaths reported. For example, it is well known to all practising physicians that the mortality varies greatly in different epidemics of such diseases as scarlet fever, measles, small-pox, whooping-cough, yellow fever, etc., the variations appearing to depend principally upon the particular conditions of the environment as to temperature, moisture, winds, density of the population, etc., at the time of the outbreak, and also upon particular conditions of the specific virus or micro-organisms causing diseases of this kind.

Take, for example, the spread of yellow fever in Texas and along the Gulf Coast during the year 1867. Here the specific cause of this disease appears to have entered the United States by two distinct routes, one coming from Vera Cruz, Mexico, and the other coming from the usual

source, Havana. At that time the United States had a comparatively large number of troops along the Southern border of the country, and hence we have a series of returns showing not merely the number of deaths, but also the number of cases of sickness from this disease occurring in a given population.

Now, in those places where the disease was of Mexican origin the cases were more fatal than those of Cuban origin, "two out of every five cases of the former dying, while the mortality of the latter was only two out of seven. The ratio of deaths was 400 per 1,000 cases for the first of these groups, 284 per 1,000 for the second." [1]

For the great majority of diseases it is not possible to obtain statistics as to their prevalence among a general population. The only sources to which we can look for information of this kind are the records of the Army and Navy, of the police force in certain cities, of the employés of railroads, and of the members of certain societies having insurance against sickness. The records of the Army and Navy are especially valuable in this point of view, but they relate only to males of certain groups of ages and of a carefully selected class of population.

In the last United States Census an attempt was made to obtain on the schedules of the living population the number of those who on the first day of June, 1880, were so sick or disabled as to be unable to pursue their ordinary occupations. This was the first attempt of the kind which has been made in this country, but similar attempts were made in two censuses in Ireland, in a census of the Australian Colonies, and in a census of Hungary.

The first examination of the United States schedules seemed to show that the returns of the sick were too imperfect and too inaccurate to permit of drawing any conclusions from them. But subsequently it turned out that they were really more complete than had been supposed, and a sufficient number were compiled for different parts of the country to obtain a fair sample of the general results. This compilation showed that for the total population over fifteen years of age the number found sick out of every 1,000 living varied from 7.17 to 22.7 for males, and from 8.1 to 17 5 for females, or about 1⅛ per cent of males and 1¼ per cent of females. These do not include the blind, deaf and dumb, insane and idiots, and it is probable that the figures do represent very fairly the different proportions of sickness occurring in males and females, and in certain groups of ages at the time that the census was taken, which, it must be remembered, was at a period when there is probably the least amount of sickness and disability among adults.

From the results of data derived from mutual benefit societies in England it has been estimated that for every case of death in a community there are two persons constantly sick; that is to say, there is an average of two years sickness to each death, or that if the annual death-rate is 18 per 1,000 the average number constantly sick is about 36 per 1,000.[2]

By the census reports the proportion of sick to 1,000 of population of different ages was as follows:

| Age. | Males. | Females. |
|---|---|---|
| 15 to 25 | 6.9 | 6.8 |
| 25 to 35 | 8.6 | 9.7 |
| 35 to 45 | 12.2 | 11.5 |
| 45 to 55 | 16.8 | 14.4 |
| 55 to 65 | 25.5 | 20 4 |
| 65 and over | 44.5 | 35 3 |

[1] War Department, Surgeon-General's Office, Washington, 1886: Circular No. 1., page xviii.

[2] Mr. T. R. Edwards (London Lancet, 1835-36, i., p. 855), from the study of a series of returns from friendly assurance societies, claimed that, for large numbers of people, there is a constant ratio of sickness peculiar to each age, and that the duration of each case of sickness at any age is in proportion to the mortality at that age. His theory is that the mortality at any year of age exceeds that of the preceding year by 2.999 per cent., or that the mortality during any decennial interval of age exceeds that of the preceding decennial by one-third part; or that the mortality rate doubles in 23½ years. According to his theory, if a physician loses by death double the proportion of patients at the age of forty-three that he does at the age of twenty, the effect of his remedies in each case is the same.

This corresponds, in a general way, to the conclusions of Mr. A. G. Finlayson relative to the amount of sickness in members of friendly societies, printed in 1854.[1]

He found that, taking the whole mass of male members of friendly societies, from the age of 15 to that of 85, about five years of sickness occurs to each man during this 70 years; but during the period of labor, from the commencement of the sixteenth year of age to the close of the sixty-sixth, there are in this 51 years but 78 weeks of sickness, or about one and a half week per annum; and the sickness occurring from 42 to 66 is almost double that occurring in the first half from 15 to 41. Hence he concludes that the sickness of the first 25 years of working life is almost exactly one-half of that of the second 25 years. In the class devoted to heavy labor the sickness is almost a year more, or in the proportion of 11 to 9 as compared with the sickness undergone in the class engaged in light labor.

It is also to be observed that during the early years of life, say from 21 to 41, the number of persons withdrawing, or excluded from such societies, is very large, being nearly five times the number of deaths. As the age of the members increases the departures become fewer, because it becomes more of an object to remain connected with the society, since the rate of annual payments is the same for all ages, while the proportion of sickness steadily increases, as we have seen, with advancing age.

Several attempts have been made to induce physicians to keep a record of all the cases they treat, but with very little result. In 1857 the Metropolitan Association of Health Officers in London carried out a systematic registration of all cases of sickness which received attention at the public expense, as in hospitals, dispensaries, almshouses, etc. About one-half of the hospitals and dispensaries in the district contributed information, but the enterprise broke down before the end of the second year, and while results gave some interesting indications for the time as to the prevalence and progress of certain forms of epidemic disease, the records have very little statistical value, as they have no definite relation to the numbers of the population furnishing the cases of sickness.

It is very improbable that anything like complete returns of sickness will ever be obtained for any large body of the civil population. Such registration will always be confined to infectious and spreading diseases; in other words, those which are known or supposed to be preventable. In order to make a registration of this kind of any great practical value it must be continuous and compulsory. The plan of endeavoring to get the medical men of a locality to voluntarily contribute this information, even when accompanied by the offer of the payment of a fee, has produced partial and incomplete results, which become more and more incomplete as time goes on, and the first enthusiasm in favor of the new plan dies away.

The various systems of compulsory notification which have been tried are, first, to require the medical attendant only to furnish the returns to the Health Office; second, to require the householder, or head of the family, to make such returns; third, to require both the doctor and the householder to make such returns; and, fourth, to require the doctor to certify to the householder, and the latter to notify the health authorities.

The Infectious Disease Notification Bill, passed by the English Parliament in 1889, is the latest attempt to solve this difficult question.

It provides that where an inmate of any building used for habitation is suffering from a disease to which the act applies, then, unless such building is a hospital in which persons suffering from infectious disease are received, the following provisions shall have effect, that is to say:

"The head of the family to which such inmate (in this act referred to as the patient) belongs, and in his default the nearest relatives of the patient present in the build-

[1] See Insurance Cyclopedia, vol. v., p. 83.

ing or being in attendance on the patient, and in default of such relatives every person in charge of or in attendance on the patient, and in default of any such person the occupier of the building shall, as soon as he becomes aware that the patient is suffering from an infectious disease to which this act applies, send notice thereof to the medical officer of health of the district.

"Every medical practitioner attending on, or called on to visit the patient shall forthwith, on becoming aware that the patient is suffering from an infectious disease to which this act applies, send to the medical officer of health for the district a certificate stating the name of the patient, the situation of the building, the name of the head of the family or other person who appears to him to be primarily liable to give the notice under this act to the medical officer, and the infectious disease from which, in the opinion of such medical practitioner, the patient is suffering.

"Every person required by this section to give a notice or certificate who fails to give the same, shall be liable on summary conviction in manner provided by the Summary Jurisdiction Acts to a fine not exceeding *forty shillings*.

"The local authority shall gratuitously supply forms of certificate to any medical practitioner residing or practising in their district who applies for the same, and shall pay to every medical practitioner for each certificate duly sent by him in accordance with this act a fee of *two shillings and sixpence* if the case occurs in his private practice, and of *one shilling* if the case occurs in his practice as medical officer of any public body or institution."

On the part of some members of the medical profession, both in Great Britain and in this country, strong objections are urged to compulsory notification of disease, and especially to that form which requires the doctor to furnish such notification direct to the sanitary authorities. It is urged that such notification is a violation of professional secrecy; that it leads to concealment of cases of such disease and the refraining from calling in a medical attendant, and that it tends to throw the treatment of such cases into the hands of a lower class of practitioners, who are willing to run the risks of violation of the law, or, even, to make false returns for the sake of securing an increased practice. There is, however, little difficulty in keeping the information furnished strictly confidential, provided the health-officer is a man of tact and discretion, and provided, also, that the press does not insist upon being too inquisitive with regard to matters of this kind.

Any system of compulsory notification, however, which has to be continuously successful, involves two things. First, that the health-officer shall not be in any way engaged in, or connected with, private practice, so as to do away with all reluctance on the part of general practitioners reporting their private cases.

The second is that, to obtain any benefit from notification, special hospital accommodations for such forms of diseases as are reported must be provided by the community, and there must be a power of compulsory removal of patients to such hospitals in certain cases.

Undoubtedly, valuable statistical data might be obtained by the simple notification alone; but the desire to obtain statistical information will never be accepted as a sufficient ground for legislation requiring compulsory notification.

We hear very much in recent years of the proportion of deaths from zymotic diseases as a test of the salubrity or sanitary condition of a place; but as there is no general agreement as to what is and what is not a zymotic disease, and as the term rests on a theory of causation of disease which is now definitely abandoned, it should no longer be made use of. It is much better to select the mortality from certain forms of disease, and specify these, in order that we may know exactly what we are talking about and be sure that the matters compared between two localities are the same. English health-officers often use the term "seven principal zymotic diseases," by which they mean small-pox, measles, scarlet fever, diphtheria, whooping-cough, typhus fever, and enteric fever. If this is the selection it is not a good one, for it omits the diarrhœal diseases. Forty years ago, near the commencement of the speculations of Dr. Farr and Mr. Simon as to the causation of disease, nearly all of the contagious diseases were grouped together as zymotic diseases, and were supposed to be more or less connected with filth. At present we know that the cleanliness of the surroundings has little or nothing to do with the prevalence of small-pox, measles, scarlet fever, or whooping-cough; so that these, which are typical zymotic diseases, are of very little interest in connection with the question as to local causes of disease in a place, connected with uncleanliness, and to be remedied by sanitary effort.

Their relative prevalence, and the mortality due to them, is of interest in a totally different connection, and their separation involves an entirely different field of sanitary work. Such diseases as phthisis, diphtheria, and the various forms of diarrhœal disease, including cholera infantum or the summer diarrhœa of children, of England, are of especial interest as regards the field of local sanitary work in relation to sewerage, drainage, and cleanliness.

The influence of habitation upon death-rates, and on the prevalence of certain forms of disease, is indicated by statistics given by Dr. Korosi for the city of Budapest, where the deaths are reported with the following classification, viz.:

1. Persons in a habitation where, at most, two persons dwell in one room.
2. Persons dwelling where from two to five persons dwell in one room.
3. Where there are from five to ten in a room.
4. Where there are more than ten in a room.

The first class includes the rich and well to do. The others present increasing grades of overcrowding. Of each 10,000 deaths reported, 1,941 belong to the first, 5,759 to the second, 2,167 to the third, and 133 to the fourth; and these ratios may be used to compare with the proportions of deaths from any disease or group of diseases as occurring in the different classes.

Comparisons thus made indicate that contagious diseases, with the exception of scarlatina and typhus, are more frequent and more fatal in the crowded houses, and that the same is true of congenital debility and diarrhœa, while tuberculosis and pneumonia do not seem to be especially influenced by this cause. (?!). As the figures of death in these categories are not comparable with those of the living population, the results have not much value.[1]

Suppose, now, that we are studying the death-rates of a city for a series of years in order to determine whether its sanitary condition is, upon the whole, improving; whether work which has been done in the way of introducing sewerage, or improved water-supply, or special precautions in dealing with contagious diseases, have had an evident good effect, and have produced results which are, on the whole, satisfactory in proportion to their cost. It is very evident that we must have something more than the mere gross death-rates for the whole population in order to form an intelligent opinion on these points. A gross death-rate may, it is true, give a correct answer to the question as to whether the sanitary condition is improving, but we can never be sure of the correctness of this answer until we have made detailed comparisons of the mortality by age and sex, and of that due to certain great classes of disease.

What has been the influence of modern civilization upon the average duration of human life? upon rate of increase of population? upon the average health and vitality of the races which it has affected? The present population of the world is between one thousand five hundred and one thousand six hundred millions, of which there are in Europe over three hundred and fifty millions, and of

[1] Korosi: Influence des habitations sur les causes des décès, etc. Paris, 1877.

European stock in other countries one hundred millions; in all, say, four hundred and fifty millions, as against one hundred and fifty millions in 1788.[1]

Evidently the birth- and death-rates now prevailing in Europe and the United States cannot have long continued, for if we suppose a population to double itself only once in a century, a million of people, living one thousand two hundred years ago, would have developed into a population of over four thousand millions by this time.

What, then, is the difference between the expectation of life in New York at the present day and that in European cities one, three, five, ten, or twenty centuries ago? This question has been asked in various shapes many times, and many attempts have been made to answer it; the general conclusion being that there has been a very great increase in the average longevity of man in civilized countries, not only within the last thousand years, but within the last century. Notwithstanding, it must be confessed that the statistical records bearing on this point are very incomplete, vague, and unsatisfactory, and that it is only for the last forty or fifty years that we can speak with anything like scientific precision as to the amount of progress made.

So far as what is termed potential longevity, that is to say, the maximum duration of life possible in an individual of the race, is concerned, there is no evidence that this has changed for at least two thousand years, being for man generally taken as one hundred years. You will remember the scriptural declaration that the years of a man are threescore years and ten, and though by reason of strength they be fourscore years, yet is their strength labor and sorrow; notwithstanding, there are sufficient records to prove that even in those days the potential longevity of man was as great as it is at present.

But when we come to the average longevity and expectation of life at birth, there is sufficient evidence to indicate that it has increased; but whether this is due to the preservation of more infant-lives for a few years, although they may still die before the productive period is reached, or to an increase of the number of those who live into and share the working period of life, is still uncertain, for this question can only be settled by comparative life-tables, and I have already explained that we have no reliable life-tables that are much over fifty years old.

I have already referred to the average duration of life among the better class of Roman citizens as fixed by Ulpian, being equal to thirty years. Among the oldest data which we possess, from which we can attempt to compare death-rates of past centuries with those of the present, are the records of Geneva in Switzerland, which date from 1551. The average annual death-rate per 1,000 was as follows:

| | |
|---|---|
| From 1551 to 1600 | 40 |
| From 1601 to 1650 | 37 |
| From 1651 to 1700 | 35 |
| From 1701 to 1750 | 33 |
| From 1751 to 1800 | 29 |

From 1801 to 1813 the mean duration of life was thirty-six years and six months.

From this, the probable duration of life is given as follows:[2]

| Periods. | Probable duration of life. Years. | Months. | Days. | Proportionate increase. |
|---|---|---|---|---|
| End of the sixteenth century | 8 | 7 | 26 | 100 |
| End of the seventeenth century | 13 | 3 | 16 | 153 |
| 1701 to 1750 | 27 | 9 | 13 | 321 |
| 1751 to 1800 | 31 | 3 | 5 | 361 |
| 1801 to 1813 | 40 | 8 | 0 | 470 |
| 1814 to 1833 | 45 | 0 | 29 | 521 |

The figures are not sufficiently full or accurate to justify the conclusion that the probable duration of life in this place has been increased five times in three centuries, but they do indicate a very marked and progressive increase.

[1] See Giffen, Jubilee Volume of Statistics, 1885, p. 99.
[2] Mallet: Annales d'Hygiène, 1837, vol. xvii., p. 5.

In the sixteenth and seventeenth centuries Geneva had a small population, frequently exposed to fatal pestilence, and produced a comparatively large number of infants, of whom but a very small proportion reached the age of puberty.

In the early part of the eighteenth century the average mortality of all European countries, taking towns and villages together, is estimated by Süssmilch as 1 in 36, or 27.778 per 1,000.

The most important contributions to our knowledge of the increase in the duration of life in recent years is contained in a paper on the decline in the English death-rate, by Noel Humphreys, published in the *Journal of the Statistical Society*, in 1883; and in a report by Dr. William Ogle, in a supplement to the Forty-fifth Annual Report of the Registrar-General of England, published in 1885.

The conclusions, as based upon English life-tables, comparing periods from 1838 to 1854, and from 1871 to 1880, are as follows:

The mean after-lifetime of a male at birth was for the first period 35.91 years, for the second, 41.35, showing an average gain of nearly a year and a half. The mean after-lifetime continues longer in the second period than in the first for each year of life until the nineteenth. At the close of the nineteenth year the expectation of life was exactly the same in each period, viz., 40.17 years. From that time onward the after-lifetime is shorter in the recent period than in the older one; that is to say, the individual male in England lives on an average a shorter time after he is nineteen years old than he did forty years ago; but the number of males out of equal numbers at the start who survive to live these shorter lives is very much greater than it was formerly, so that the aggregate life of the whole is considerably increased. The gain is greater in females than in males. Thus in the first period the expectation of life in females was 41.85, while in the second period it was 44.62, being a gain of 2.77 years on an average for each female. The after-lifetime continues longer in the new period down to the completion of the forty fifth year, when the expectation of life becomes the same, viz., 24.06.

Taking a million males and a million females, the following table shows the additional years gained at each age-group, for each sex, during the recent period.

| Age periods. | Males. | Females. |
|---|---|---|
| 0 to 15 | 255,340 | 288,226 |
| 15 to 25 | 281,872 | 339,933 |
| 25 to 35 | 344,906 | 453,221 |
| 35 to 45 | 310,746 | 499,471 |
| 45 to 55 | 211,040 | 474,009 |
| 55 to 65 | 86,920 | 385,257 |
| 65 to 75 | 10,464 | 239,617 |
| 75 to 85 | 27,770 | 89,568 |
| 85 and upward | 13,451 | 8,282 |
| Total years gained | 1,439,139 | 2,777,584 |

This table shows plainly how erroneous is the conclusion sometimes drawn that, because the death-rates have fallen only in the earlier age-periods, while they have risen in the later age-periods, the aggregate gain to the community from the changes is confined to the unproductive years of life. We may fairly take the period which intervenes between twenty-five and sixty-five years of age to be the most valuable part of life, and of the aggregate years saved, 66 per cent. in the case of males and 65 per cent. in the case of females are lived in this period.

The earliest attempt to give vital statistics for the United States is probably a paper by Edward Wigglesworth, published in the "Memoirs of the American Academy of Arts and Sciences," 1793, vol. ii., page 131, entitled "A Table showing the Probability of the Duration, the Decrement, and the Expectation of Life, in the States of Massachusetts and New Hampshire, formed from Sixty-two Bills of Mortality on the Files of the American Academy of Arts and Sciences in the Year 1789." The whole number of deaths reported on these bills was 4,893.

He had no data of population, but the reports indicated that the births in the locality sending the bills were twice as many as the deaths. As his calculations are based solely on the deaths alone at certain ages, the conclusions are evidently entirely unreliable; but, such as they are, they are as follows:

The expectation of life at birth was 28.15 years; at five years, 40.87; at ten, 39.23; at fifteen, 36.16; at twenty, 34.21.

By another calculation he finds that the expectation at birth was 35.47, and at five years of age 48.46.

Another paper is by J. E. Worcester, printed in the "Memoirs of the American Academy of Arts and Sciences," Philadelphia, 1833, vol. i., New Series, page 1, and entitled "Remarks on Longevity and the Expectation of Life in the United States, relating more particularly to the State of New Hampshire." Taking the bills of mortality of thirty-two townships in New Hampshire for an average length of time of twenty-one years, he found that the death-rate was 1 in 83, or 12.04 in 1,000. He wisely remarks that the ratio is so small as to excite suspicion concerning the accuracy of the bills.

With this may be contrasted the following table showing the expectation of life in Massachusetts as computed from the deaths occurring in the five years 1883–87, compared with the living population in the middle of this period as deduced from the Massachusetts census of 1885.

*Expectation of Life.*

| Ages. | Massachusetts, 1883-87. | | | City of Baltimore, 1880. | | | | | | New York City, 1879-81. | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | White and Colored. | | | White. | | | Colored. | | | White and Colored. | | |
| | Persons. | Male. | Female. | Persons. | Male. | Female. | Persons. | Male. | Female. | Persons. | Male. | Female. |
| 0 | 40.87 | 39.72 | 42.03 | 38.18 | 36.49 | 39.86 | 23.26 | 21.00 | 25.51 | 30.90 | 29 04 | 32.77 |
| 1 | 49.77 | 49.43 | 50.12 | 46.04 | 44.73 | 47.36 | 35 32 | 32.20 | 38.44 | 39.66 | 38.22 | 41.09 |
| 2 | 52.67 | 52.36 | 52.98 | 49.80 | 48.42 | 51.18 | 41.91 | 39.25 | 44.57 | 44.04 | 42.59 | 45.49 |
| 3 | 53.02 | 52.73 | 53.31 | 51.05 | 49.77 | 52.33 | 43.66 | 41.19 | 46.13 | 45 39 | 43.93 | 46.85 |

One of the most frequent fallacies in the use of statistical data is to mistake an effect or a coincidence for a cause. For example, it is common to speak of rapid growth in population of a locality or country as if it were in itself a good and desirable thing, a cause of prosperity and well-being, and when this growth lessens or ceases we find some philosophers trying to devise ways and means to increase it. This, for example, has been the case in France for a number of years, and various plans have been proposed for increasing the birth-rate and diminishing the death-rate, in order to produce prosperity and strength in the country. The fact is that rapid increase of population in a country is an indication that things are going on well there, that there is a demand for labor, and that men find that they can increase their comfort by going, or staying, there; but it may, or may not, be a cause of prosperity at a given time, and sometimes it may cause hardship, weakness, and suffering.

You are all, no doubt, familiar with what is known as the Malthusian theory, which is, essentially, that population is limited by the means of subsistence available, that population increases in a geometrical proportion, while the means of subsistence do not increase in a faster ratio than arithmetical progression; that, therefore, the growth of population is checked by want of means of subsistence, and, therefore, that the increase of mankind may be considered as the chief source of misery, which misery, together with moral restraint to a limited extent, and vice, check the superior growth of population, keeping it at a level with the means of subsistence.

If this doctrine be applied to the lower animals or to an extremely savage and ignorant set of men, it is very nearly correct; for, in this case, the term "means of subsistence" applies almost exclusively to the natural produce of the earth. As soon, however, as man applies his intelligence to the increase of the means of subsistence by improvements in agriculture, by manufactures, etc., it is no longer true that the means of subsistence increase in an arithmetical proportion. They may increase, and, for the last fifty years have, throughout civilized regions of the world, actually increased in a ratio more rapid than geometrical proportion and more rapid than the increase of population; and it is, therefore, substantially true that "the character of every race of men is the real limit to its numbers in the world, if allowance be made for accidents of position and time."[1]

The uneducated and unskilled laboring classes who are without capital, when gathered together in large masses, tend constantly to illustrate the theory of Malthus by increasing faster than they can provide means of subsistence for themselves and their families.

But this tendency is opposed by the advance in knowledge, increase in energy, and improvement in inventions in the educated classes, who, although it may be said that they are acting only from selfish interests, are, nevertheless, led by those interests to expand the fields of agriculture, manufactures, and commerce, and, thus, to both increase the means of subsistence and to lessen the price thereof.

Under favorable conditions a population is capable of doubling its number every twenty-five years. In the United States, between the years 1790 and 1860 the population doubled itself about once in 23½ years. But a proportion of this increase was due to immigration.

Whether in the future a systematic attempt to maintain an equilibrium between subsistence and population will become a practical problem of national policy is, at present, a purely theoretical speculation, for it is very easy to show, as has been done by Mr. Atkinson, that the means of subsistence at present at our command can easily be quadrupled, as the increase of the population occurs to both require and produce such increase.

Note.—In estimating the progress of the population of the United States for the next century, if we assume a rate of 33.3 per cent. of increase in ten years, which is a

[1] Farr: Vital Statistics, London, 1885, p. 15.

little less than the mean rate for the last century, we find that the probable population in 1990 will be 1,206,562,248, giving a density of population of 399 to the square mile, approaching the present density of China, which is 420, or of Belgium, which is 434 per square mile.

NOTE.—Maria Mitchell, in a recent number of the *Century*, speaking of an interview with Sir John Herschel, says that, one morning at the breakfast-table, Herschel put the following question: Suppose that since the time of Cheops, three thousand years ago, man had only died from natural decay at about ninety years of age, and that the population doubled itself every thirty years; starting with a single pair at the time above referred to, would the present surface of the earth afford standing room to the entire progeny if closely packed? The replies to this conundrum were various; one saying that they would occupy a layer three feet deep, another a layer fifty feet high, and so on, extending the guesses as he said, "More, more," to the distance of the moon, to the sun, and finally to the planet Neptune, when his reply was that they would have piled up upon the surface of the earth to a distance equal to one hundred times the distance of the earth from the planet Neptune.

One of the most interesting and important questions in vital statistics in this country is that relating to the relative increase in the white and colored population in the Southern States, and the influence which has been, and will be, exerted upon this by the abolition of slavery. On the one hand, it is claimed that the large increase in the colored population between 1870 and 1880 indicates that in fifty or, at most, a hundred years more it will greatly predominate.[1] On the other, it is affirmed that the greater increase of the colored population is apparent rather than real.

The following table will aid in forming an opinion on this point; but we must wait until we know the results of the next census before coming to any conclusion.

*Table showing Percentage of Increase of White and Colorea Population in Certain Districts.*

| District. | 1840–50. | | 1850–60. | | 1860–70. | | 1870–80. | | 1850–80. | | 1860–80. | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | White. | Colored. | White. | Colored. | White. | Colored. | White. | Colored. | White. | Colored. | White. | Colored. |
| I. | 20.92 | 9.47 | 18.72 | 7.24 | 11.35 | 4.16 | 26.54 | 27.57 | 67.28 | 42.42 | 40.90 | 32.88 |
| II. | 35.73 | 27.16 | 33.15 | 14.50 | 29.49 | 3.91 | 24.77 | 23.74 | 115.60 | 47 23 | 61.54 | 28.58 |

| IV. | .... | .... | 67.90 | 59.32 | 14.79 | 9.43 | 62.90 | 46.79 | 213.90 | 155.90 | 86.97 | 60.63 |
| Total | 26.96 | 19.73 | 30.13 | 22.47 | 16.90 | 7.67 | 32.87 | 34.38 | 102.14 | 77.20 | 55.33 | 44.68 |

District I. includes Delaware, Maryland, District of Columbia, Virginia, West Virginia, and North Carolina.
" II. " Kentucky, Tennessee, and Missouri.
" III. " South Carolina, Florida, Alabama, and Georgia.
" IV. " Mississippi, Louisiana, Arkansas, and Texas.

In examining these figures it must be remembered that the census of 1870 was very imperfectly taken in many of the Southern States, and that the apparent great increase in the negro population is largely due to the incomplete enumeration of the negroes in 1870. Hence I prefer to compare the period 1840–60 with 1860–80, instead of using the ten-year periods. It is also to be remembered that migrations have affected the whites more than the negroes. Many more whites than negroes have left Group III., and the increase of population in Texas is largely due to white immigration.

We have little information of value relative to the vital statistics of the colored population in the South previous to the abolition of slavery. The only two Southern States having registration laws which were to any extent enforced were Kentucky and South Carolina. The Kentucky reports relating to the registry and returns of births, marriages, and deaths are eight in number, commencing January 1, 1852, and extending to December 31, 1859, the last report being printed in the early part of 1861. The South Carolina annual reports of registration of births, deaths, and marriages begin with the year 1853 and end with the year 1859. In neither State was the registration of either births or deaths in any year sufficiently complete to permit of accurate comparisons with the number of living population, either for the whites or blacks.

The conclusions drawn by the registrars may be summed up in the statement that the birth-rate of the slaves was much greater than that of the whites in South Carolina, while the difference was not marked in Kentucky; that in both States the death-rate of the negro was decidedly greater than that of the whites, especially in infancy, and that the average age at death was decidedly higher in the whites.

I have already shown the fallacies connected with taking the average age at death as a means of judging either the healthfulness of a locality or the expectation of life. Notwithstanding, this is practically the only ratio to which we can refer in regard to the question under consideration. In the last South Carolina report for 1859 the proportions are as follows:

| | |
|---|---|
| One birth in a population of | 48.27 whites. |
| " " " " " | 26.05 slaves. |
| " " " " " | 32.34 of both races. |
| One death in a population of | 136.82 whites. |
| " " " " " | 59.20 slaves. |
| " " " " " | 77.95 of both races. |
| Average age at death | 28.42 years in whites. |
| " " " " | 14.87 years in slaves. |
| One marriage in a population of | 169.90 whites. |

In the last Kentucky report it is stated that the average age at death was, for the whites, 21.21 years, and for the blacks, 18.27 years.

The records of the statistics of 1880 show that the birth-rate for the year was greater in colored than in the whites; since in the ten groups in which distinction of color was made for this purpose the birth-rate for the whites was 32.0, and for the colored, 38.06, per 1,000 of aggregate population; or for the whites, 127.1, and for the colored, 163.8, per 1,000 of women between the ages of 15 and 49. The birth-rate is always higher among the poorer classes of a population, and it is doubtful whether the birth-rate of the negro is higher than that of the laboring classes among the whites. The mortality among the colored infants in the earlier months of life is much heavier than among the whites in the same localities. For example, in the ten grand groups just referred to, out of each 1,000 infants born the number which died under six years of age was, for the whites, 66.7, and for the colored, 71.4. This fact tends to increase the birth-rate among the colored, because with the loss of the infant, and consequent cessation of nursing, the probabilities of a fresh pregnancy increase. The marked difference between the vital statistics of the white and colored in the South is much greater in the cities than in the rural districts, as will be seen from the following table.

The average mortality in a population of a little over 43,000,000 whites was recorded as 14.74 per 1,000; while in a population of 6,752,000 colored the recorded mortality was 17.28 per 1,000. It is known that each of these recorded death-rates is much lower than the actual one, owing to failure to record the whole number of deaths

[1] See paper by E. W. Gilliam, Popular Science Monthly, xxii., 433.

occurring during the census year; but it is also known that the proportion of failures to record was decidedly greater among the colored than among the whites, and hence the difference between the death-rates of the two races is even greater than that indicated by these figures.

two races under comparatively similar circumstances than we now have.[1]

The data are insufficient to bear out any definite conclusions and the above can properly be put in the form of questions only.

*Birth-rate per* 1,000 *of Living Population.*

| | Aggregate population. | | Birth-rate per 1,000 of living population. | | Increased percentage of colored births. | Increased percentage in urban over rural counties. | Born and dying during census year per 1,000 births. | | Increased proportion of colored infants born and dying during census year. | Increased proportion in urban over rural counties. |
|---|---|---|---|---|---|---|---|---|---|---|
| | White. | Colored. | White. | Colored. | | | White. | Colored. | | |
| Twenty-three counties in the South containing cities and large towns. | 588,129 | 586,038 | 28.71 | 35.08 | 6.37 | 1.22 | 100.01 | 140.06 | 40.05 | 11.66 |
| Fifty-one counties in the South containing very small towns | 542,705 | 591,336 | 34.31 | 39.46 | 5.15 | ... | 62.66 | 91.0 | 28.39 | ..... |

How far is this excessive mortality in the colored population due to race characteristics? Is it due to peculiar susceptibility on the part of the negro to certain distinctive forms of disease, or to his having less vital force and capacity to resist disease and death? Undoubtedly the great mass of the colored population is poor and ignorant, lives in the dampest and dirtiest parts of cities, and in the midst of unhealthy surroundings, and is in other respects unusually exposed to well-recognized causes of disease.

The statistics of 1880 show that the colored race is peculiarly liable to fatal results from certain forms of disease, especially consumption, pneumonia, diarrhœal diseases, affections of pregnancy, scrofula, and venereal diseases; and that, on the other hand, it is much less liable than the white race to fatal results from cancer, diphtheria, diseases of the nervous system, scarlet fever, and suicide.

Notwithstanding the interest and importance of the question, we have at present no sufficient data to determine whether the negro, under the same circumstances as to poverty, etc., is, or is not, more prolific or short-lived than the whites, and absolutely no data of any value for determining the relative fecundity and mortality of the mixed bloods, including mulattoes, quadroons, octoroons, etc. An effort will be made in the coming census to supply this deficiency as far as possible. In the enumeration of the population those of mixed blood will be recorded separate from the pure blacks and the pure whites, and an effort will be made to obtain corresponding records of death in order to determine the death-rates of these mixed bloods. An effort will also be made to determine the birth- and death-rates of certain classes of poor and ignorant whites, such as the tenement-house population in our Northern cities, as distinguished from those of the mass of the white population, which will give us a better means of comparison of the mortality of the

In studying the causes of disease and death in communities, a very important point to be considered is the relative poverty, ease, or luxury in which different parts of the population live—or the sickness and death-rates of so-called social classes.

That extreme poverty, producing inability to obtain the amount of food, clothing, and shelter requisite to preserve health is a direct cause of high death-rates, especially in Northern climates, is known to all; but the extent to which this factor of want influences the death-rates in different countries or communities is by no means easy to determine, and thus far we have, for the most part, only data bearing indirectly upon this subject. For the provident and presumably well-to-do classes we have the statistics of life-insurance companies; but these are for selected lives, which fact tends to give a low death-rate during the early years of the policy-holders, while, on the other hand, the tendency to cease paying annual dues and to give up the insurance is greater in those who are well and strong than in those who have reason to suspect that they are diseased, so that the death-rates in the greater ages are higher in the insured than in those not insured. We can only draw some inferences from the vital statistics of occupations, from tenement-house statistics, etc.; but it is very difficult to distinguish between effects of density of population, occupation, race, intemperance,

*Annual Rate of Mortality in Various Classes of the Population of Dublin at Different Age-periods during the Four Years* 1883–1886.

| Occupation or social position. | | AGE. All ages. | 0 | 5 | 20 | 40 | 60 and upward |
|---|---|---|---|---|---|---|---|
| All persons | Years of life | 1,406,124 | 151,853 | 400,111 | 490,174 | 260,459 | 103,527 |

[1] Dr. Berenger-Feraud, in a note on the fecundity of the mulattoes of Senegal, published in Revue d'Anthropologie, 2d Series, vol. ii., 1879, page 577, gives the details with regard to the offspring of 118 females of mixed blood, and concludes: 1st, That the union of a white man with a negress in Senegal produces children apparently of good health; 2d, the offspring of these mulattoes between themselves, when there is no further intrusion of pure black or white blood in the descent, gives children who are usually sterile; 3d, when there is a new addition of white blood after the first generation, the offspring are less vigorous, the number of the girls becomes greater than that of the boys, and the girls are often sterile with a strong tendency to abortion.

uncleanly habits, and actual want of the necessaries of life.

One of the latest systematic attempts to enumerate the population of a city by social classes, and to obtain corresponding reports of deaths so as to give death-rates, is that made in Dublin by Dr. Grimshaw, the results of which are shown in the table opposite :[1]

In this connection may be mentioned the statistics collected by insurance companies among the Quakers or Society of Friends, both in England and in this country.

In 1830 Mr. Robert Rankin published a table showing the probability of life among the Society of Friends in the city of Bristol, England.

The superior expectation of life shown in this city led to the establishment of a Friends' Provident Insurance Institution in the following year, due to the belief that the members of this society had a superior longevity; but the parties concerned, with their usual business sagacity, did not invest money on a mere belief. They set to work and collected all the registers of Friends in different parts of the kingdom, with births and deaths, from which a table[2] was prepared showing that at birth the expectation of life was:

| | |
|---|---|
| At 5 years | 41.8 |
| At 10 " | 45.3 |
| At 15 " | 42.1 |
| At 20 " | 39.2 |
| At 30 " | 33.3 |
| At 50 " | 21.2 |
| At 60 " | 14.7 |

The tendency now is to accumulate the best and the worst of the race in the cities. They draw to them the most enterprising, vigorous, and prudent, whose tendency is to late marriages and few children, and thus tend after a time to lower the standard of the race. "Where the tendency is to replace a feeble and lower race by a better one there is progress, where the tendency is the reverse there is decay. The hope that by increased knowledge, charity, and co-operation, the feeble, the sickly, and incompetent can be so cared for that they shall become strong and vigorous, is that held by most men of the present day, but there is nothing in the laws of heredity which gives any foundation for this hope."

What is to be the outcome of this modern civilization? "Its enemies are not without but within—not savage nations on its borders, but dwellers in its own cities." The general tone of modern European literature is pessimistic as to the future, filled with doubts and fears as to what the coming supreme democracy will do. In this country it is more hopeful, and looks forward to progress in improvement in the physical conditions of the race, though admitting the dangers and difficulties which this very physical improvement tends to produce. But, whatever be the views of individual thinkers and writers, on one point all can agree, and that is as to the desirability of having at our command definite, positive information as to the character, amount, and set of currents of this stream of human life in different countries and localities. An important part of such knowledge is that which relates to the composition of, and changes in, the population in different countries, which is the special field of vital statistics.

(To be continued.)

SYNTHETIC CARBOLIC ACID.—Carbolic acid is now prepared synthetically by a German chemical house. It is claimed that many of the unpleasant effects of the ordinary carbolic acid are due to the impurities that it contains, and that these are not produced when the synthetic preparation is used, as the latter is chemically pure.

## ONE OF THE CAUSES OF TYPHOID FEVER.

BY WM. THORNTON PARKER, M.D.,

NEWPORT, R. I.

VON GIETL, in his work[1] "Die Ursachen des Enterischen Typhus in München," defines typhoid fever as "a specific, putrid, intoxication disease (Intoxications-krankheit), which is composed of a chain of diseased processes which are dependent upon one another, but which do not retain a regularity either in number or in succession. Its local effect is a catarrh of the alimentary canal; the further and peculiar result a swelling of the glandular apparatus as well of the mesentery as the mucous membrane of the intestines. Exfoliation and ulceration generally follow, the final effects being mortification in all degrees. The lower grades of typhoid infection agree perfectly in their manifestations with the simple form of putrid infection. These last originate by inhaling and swallowing air already vitiated with foul odors, and loaded with poisonous materials. A most frequent cause of this is to be found in little, narrow, over-filled sleeping-rooms, with closed doors and windows, or when in these rooms decaying materials are to be found, or the vapors penetrating the atmosphere of the room from outside. Moreover, the typhoid fever is also putrid infection, but with specific character that manifests itself through the engendering of a specific poisoning in the body sick, and thereby affording immunity from a second attack; therefore the typhoid must have a certain individuality. Whether the typhoid fever can originate by a collection of certain favorable circumstances recognizable, or whether its germ must be taken into the system, is at present unknown. Observation has, up to the present time, been unable to solve the question, but it is beyond doubt that foulness animates the typhoid poison and favors its development. Observation proves further that fecal material finding its way into drinking-water caused the severest form of typhoid; that the typhoid fever can remain resident and persistent in a house for years; that now and then, in hospitals, barracks, or tenement houses, the infection locates itself in certain rooms while those occupying the neighboring rooms escape altogether." These are but a few quotations from the admirable work of Von Gietl already alluded to. No man has had greater opportunities to study and investigate typhoid fever, and no one has more faithfully improved such opportunities than Von Gietl. The teacher of Lindwurm, Liebermeister, Von Ziemssen, and many other more or less distinguished in researches concerning typhoid fever—how seldom we see his name quoted! The master-mind as professor of general medicine at the University of Munich, and in charge of the great wards of the General Hospital of that city, where there is more typhoid fever to be studied than in any other city in the world, Von Gietl's opportunities certainly were extraordinary. Pepper, in his admirable "System of Medicine," quotes Budd, the student, but not the master. Fagg refers to Von Gietl as well as to Budd, his student, and states that the Munich theories are now widely adopted. I should like to quote more from Von Gietl's work, for it is worthy of more careful notice, although many who believe in the bacillus typhosus would consider Von Gietl's conclusions altogether too old-fashioned for them. And yet one at least of the old-fashioned conclusions of Von Gietl has been brought very forcibly to mind by the recent fatal outbreak of severe enteric fever on the U. S. S. New Hampshire.

As a student of von Gietl in Munich, in 1872 and 1873, I well remember one of his theories concerning the origin of this fearful disease. Those who have visited the large houses of Munich, and of other German cities, still re-

[1] Conclusions concerning the Causes of Typhoid Fever in Munich, by Professor Von Gietl, translated by W. Thornton Parker in The Sanitarian.

member that each house has a large privy vault, from the main shaft of which smaller passages lead to the seat of the privy. These passages are as large as a man's body until they connect with the main shaft, which is very large. A simple wooden cover covers the seat when the privy is not in use; the instant it is removed a strong current of foul air loaded with fecal matter rushes into the room. For an American accustomed to our more cleanly privies this stench is intolerable. On entering a German house we notice the halls contain more or less of this fecal odor —the rooms next to the privy, although not communicating by a door except through the hall, are noticeably odorous with fecal matter. This odor has actually penetrated through the walls, windows, and doors. Now von Gietl, upon examining a patient admitted into the General Hospital in Munich, suffering from typhoid fever, would invariably ask the patient if his room were next to a privy-room, and if he noticed a privy odor in the room. Very often the answer would be—yes.

I mention this to show that von Gietl believed that exposure to continued fecal odor, without other contagion, would develop typhoid fever. Now, there are many other old fashioned theories, pushed aside by those who are collecting the various specimens of bacilli, which are well worth remembering. It is difficult for some men, myself included, to believe that we have one bacillus for typhoid fever, another for cholera, another for diphtheria, another for scarlet fever, another for phthisis, another for gonorrhœa, and so on *ad infinitum*, until our collection of these interesting little creatures would rival in number the coins of a numismatist. More easily believed and understood is the paper of Dr. Griffith on the "Unity of Poison" in scarlet, typhoid, puerperal fevers, and diphtheria, erysipelas, sore throat; certain forms of diarrhœa and allied ailments, in pleurisy, pneumonia, and pleuro-pneumonia, and many other affections heretofore usually considered to be separate and entirely distinct diseases.

Would it not be fair to assume that the unsanitary conditions surrounding the United States ship New Hampshire were sufficient to propagate typhoid fever on board that vessel—without the appearance of the bacillus typhosus to properly start the mischief, according to the scientific theories of some of our modern investigators?

The United States ship New Hampshire is an old-fashioned "man-of-war," which, on clear blue water, might have been a safe and healthy home for double the number of men and boys who have lived on her during the past five or six years; but in an abnormal element, *i.e.*, resting in a mud-hole, and surrounded by mud and all uncleanness, and with tons of fecal matter piled up around her bows, she could hardly have been considered a safe resort for human beings. The fecal element was certainly in the majority here, and the atmosphere loaded with fecal matter entered the ports on its death-dealing mission. Her brave old sides of oak, which would have held her gallant crew in safety in the good old days, gave no protection to this new and treacherous foe, when she had been dragged from her normal element into the unnatural and filthy place in which so many of her crew received their death-wounds in the shape of typhoid fever.

It is not my intention to magnify the fact that fecal odor, or the gases escaping from large quantities of decomposing fecal matter, can produce typhoid fever, but merely to protest against the claim that, given a case of typhoid fever, the bacillus typhosus must have had some influence in its causation. That many different shaped bacilli can be found in the discharge of patients suffering from various disorders, there can be no doubt. Many admit that a sufficient quantity of these same bacilli may, under favorable conditions, induce disease; but it seems to me more reasonable to suppose that decomposition of animal and vegetable matter is more frequently the cause of preventable disease, rather than that the emigration of particular bacilli is to be the principal cause recognizable.

It is not the intention of this paper to bring forward a theory of odor as the principal causation of typhoid, or to deny the germ of disease which may go from one person to another through the medium of air, water, or food, but merely to call for a recognition of the theory of von Gietl, that fecal odor alone—if continued and sufficiently strong—can, and often does, develop typhoid fever, and that this theory has had a very startling illustration in the many deaths which have occurred from the infection received on board the United States ship New Hampshire.

I believe that true science does not tend toward such a complication of terms and theories that the average mind stands appalled on contemplation, but that knowledge simplifies and makes easy what before seemed incomprehensible; and that, even as with machinery, the attainment of the more perfect is the employment of the more simple. So, as we advance in medical science, we will discover how much of truth there is to be found in the theory of unity in disease. We have the foul conditions obtaining which I have just referred to, and at one time an epidemic of scarlet fever will result, at another diphtheria, at another more or less severe diarrhœas, and as in this instance, at another typhoid fever. Filth and health are directly antagonistic. Nature abhors filth, and strives in every way possible to get rid of external or internal waste or foul substance. Filth lowers the health, and if it be not destroyed is itself the destroyer of life; but in accomplishing this work, it may do so in many different ways and yet exhibit itself only in one exciting cause or in a combination of causes—foul air, foul water, foul privy vaults, decaying animal and vegetable matter. I believe the time will come when the remarkable exploits of the many-shaped and many-named bacilli will be one of the curiosities of medical literature. Dr. Griffith's admirable illustration of unity of poison is shown in this extract from his writings concerning the series of evolutions—symptoms—resulting from dissecting wounds received while operating on the bodies of those who have died of peritonitis: "One will die rapidly, say in twenty-four or forty-eight hours, from acute blood-poisoning; another will have multiple abscesses; another abscesses and pneumonia or pleuro-pneumonia; another the same, plus meningitis, or even in addition kidney or liver mischief in more or less acute stages; another all the preceding, plus pericardiac and cardiac affection, leaving or not, if the patient recover, permanent cardiac mischief; another, in whom a tendency to phthisis exists, will fall into true tubercular consumption—the multiple abscess stage preceding it or not in the course of evolution and development of the materies morbi."

Burdon Sanderson has shown that, starting with a simple irritant inflammation, he can produce a virulent specific poison reproducing its like and killing either by pyæmia or more slowly by tubercular disease.

## A CASE OF TUBAL PREGNANCY SUCCESSFULLY TREATED BY ELECTRICAL FŒTICIDE.

By GEORGE M. EDEBOHLS, A.M., M.D.,

GYNECOLOGIST TO ST. FRANCIS HOSPITAL, NEW YORK.

Mrs. E——, aged thirty-three, native of the United States, has always enjoyed most excellent health. She is the mother of two children, aged five and a half and three and a half years respectively. Last confinement, December 2, 1885; no miscarriages. Menstruation began when fourteen years of age, and has occurred with the most invariable regularity ever since, except when interrupted by gestation. Her last regular menstruation occurred March 22, 1889. The non-appearance of the menses four weeks subsequently, and the occurrence of slight morning sickness, led to the suspicion of pregnancy.

April 23 to 30, 1889.—Repeated severe colicky pains in lower part of abdomen, especially on right side.

May 1st.—Examination shows uterus of normal size, slightly retroverted (first degree). External os somewhat soft and slightly patulous. To right of fundus a small,

tender mass, taken at the time for a partially prolapsed, and probably inflamed, right ovary. Excessive tenderness prevented a thorough search for the right ovary in its normal position.

May 5th to 13th.—Metrorrhagia, more free than at periods, accompanied by colicky pains, and the discharge of a few small shreds.

May 13th.—Tubal pregnancy strongly suspected. Hemorrhage controlled by tamponing vagina with iodoform gauze.

May 13th to 21st.—No further hemorrhage, but persistent colicky pains, and pains down anterior parts of right thigh. Daily examination showed mass to right of uterus to be steadily and rapidly increasing in size. A positive diagnosis of tubal pregnancy of the right side was now made, based upon the following considerations: 1. The symptoms, above detailed, of an incipient gestation. 2. The development and rapid, steady growth of a tumor in the region of the right tube, where it was positively known that nothing abnormal had previously existed. 3. The accompanying of this development by metrorrhagia, labor-like pains, and the passage of shreds.

On May 22d I accompanied Mrs. E—— to the office of Professor T. Gaillard Thomas, to whom I stated my diagnosis. Dr. Thomas was prevented by pressing engagements from making an examination, an appointment for which was made for the following day. On the way home the patient was suddenly taken with the most excruciating abdominal pains, fainting, vertigo, and symptoms of collapse. Her pulse became rapid, small, and thready, and her countenance blanched. Immediately upon reaching her home, which was accomplished with the greatest difficulty, I injected fifteen minims of Magendie's solution hypodermatically. Cessation of pain and improvement of general symptoms followed. At my request Dr. Thomas very kindly saw the patient with me in the evening, made a careful examination, and confirmed the diagnosis of tubal pregnancy. He considered that an imminent rupture had been prevented by the morphine. Electrical fœticide was agreed upon as the treatment to be pursued.

May 23d.—Electricity applied by Dr. E. L'H. McGinnis, in the presence of Dr. Thomas and myself, with every preparation made for an immediate laparotomy, in case of the occurrence of untoward symptoms. A round electrode was applied in the vagina against the mass, and a flat electrode on the abdomen over the site of the tumor. The slowly interrupted galvanic current, 75 milliampères, applied for ten minutes, gave no pain, although it produced violent spasmodic contractions of muscles of abdomen and of right lower extremity.

The electrical applications were repeated in the same manner and with the same results on May 25th, 27th, 30th, June 3d and 6th—six applications in all. During this time the patient suffered much from pains in the lower part of the abdomen, more of a quiet and steady than of the previous colicky nature, accompanied by a slight rise of temperature (up to 100⅘° F.) and pains and soreness in the abdominal muscles. The latter I attributed to the violent contractions produced by the electricity. The pains on two occasions called for hypodermics of morphine for their relief.

June 2d.—Patient seen by Drs. Thomas and W. R. Gillette. The latter concurred in the diagnosis and approved the treatment.

June 15th.—Menses reappeared, normal in duration and amount, and painless.

Dr. Thomas examined Mrs. E—— toward the end of June, and verified the cessation of growth of the tumor.

November 21st.—Patient has remained perfectly well since June 6th. On two occasions excessive exertion was followed by dull pain in the right groin, lasting for one day. With this exception, there has been absolutely nothing to remind her of her former trouble. Examinations at intervals have enabled me to follow the gradual diminution in size and final disappearance of the mass, without any further treatment. To-day nothing abnormal can be found in the pelvis by bimanual examination.

I have thought it worth while to place the case on record for the following reasons: 1st. Because the subject of uterine gestation and its treatment is one of lively interest just at present. 2d. Because the diagnosis, carefully and deliberately arrived at, and confirmed by two such eminent authorities as Drs. T. G. Thomas and W. R. Gillette, cannot reasonably be questioned. 3d. Because of the entirely satisfactory results of the treatment employed—the destruction of the fœtus and its complete absorption within six months, without having exposed the mother to the perils and possible sequelæ of a laparotomy.

198 Second Avenue.

## CATARRHAL NEURALGIA.[1]

By A. G. HOBBS, M.D.,

ATLANTA, GA.

I have purposely not used the term *catarrhal headache*, or *catarrhal browache*, because both are too restrictive to cover the condition that I desire to discuss.

By *catarrhal neuralgia* I mean to include not only the headaches and browaches that are caused by the pressure from nasal hypertrophies or foreign growths, but all reflex pains that have for their origin pressure in the nasal cavities, whether they be located in the forehead, the temples, across the bridge of the nose, or over the cheek-bones. That such reflex pains do occur, and have for their cause pressure in the nasal cavities, was known long ago, and I might quote authorities, but I consider that to do so, before the Fellows of this Association, would be an unnecessary waste of time. When we consider the great number of sensitive nerves, with their different sources, that supply the nasal and adjacent mucous membranes, reasoning from the abstract we might conclude that reflex pains would be caused by any pressure upon these mucous membranes and their underlying tissues, but I am sure that I am warranted in saying that it is the *experience* of everyone here that such pains not only exist, but have their origin in nasal hypertrophies or neoplasms. If these pains were only occasional, or of short duration, they might not demand so much of our attention, but in many cases the pains are more persistent than the neuralgias from any other cause, and they, many times, produce a more profound impression upon the general system, indicated by a sense of lassitude, a haggard expression, a malassimilation, and a decided loss of weight.

Much has been written recently on headaches and browaches caused by uncorrected errors of refraction, and it cannot be denied that such reflex pains, often accompanied by nausea and dizziness, frequently have their origin in asthenopia and astigmatism. Such symptoms are reflex in character and have their origin in the ciliary region of the eye, a part so abundantly supplied with peculiarly sensitive nerves. While we should not be hasty in diagnosing the origin of such reflex symptoms, I do not consider it difficult to differentiate between the eye and the nose, as the cause, when the two do not coexist. Ocular headaches are more intermittent, usually following a prolonged use of the eyes; catarrhal neuralgia persists longer at each attack and usually follows a coryza. Ocular headaches, if severe, are often accompanied by nausea and dizziness; catarrhal neuralgia rarely, if ever, causes the latter symptom.

When the eye is the cause, the pain is situated in the front part of the head and temples; when the nose is the cause, the pain is not only in the head and temples, but it may extend downward into the facial bones. Both causes may coexist in the same case, when relief can be effected only by both correcting the error of refraction and reducing the nasal pressure. In such a case only a partial relief would be reached if either of the causes were neglected.

[1] Read at the Seventh Annual Meeting of the American Rhinological Association, Chicago, October 11, 1889.

I have no statistics bearing upon the comparative frequency of catarrhal and ocular neuralgias other than my own note-book of the last three years. In it I find 54 cases under the combined headings: *Catarrhal neuralgia, ocular headache, and catarrhal and ocular neuralgia combined.* Thirty-six cases occur under the first caption; 14 cases under the second, and 4 cases under the third.

My recollection is that I have placed no one of these cases under its respective heading except where the patient applied particularly for relief from some of the above-mentioned neuralgic symptoms. In the great majority of these cases the patient had no clear idea of the cause of his trouble, and, indeed, in many of them, he had "gone the rounds," and had taken all the anti-neuralgic remedies mentioned in therapeutics, or, I might say, mentioned in the current circulars of enterprising drug-houses. It may be that the preponderance of catarrhal over ocular neuralgias, occurring in my note-book, is due to the fact that I treat more nasal than eye cases; but it is my opinion that the nose, more frequently than the eye, is the cause of the reflex neuralgias.

After recognizing the etiology of a case exhibiting these reflex pains, on account of the severity of the pain, temporary relief should be given the patient by the application of cocaine sprays, or, in the case of complete stenosis, the cotton probe saturated with cocaine first, then the sprays. The effect should then be to reduce the pressure permanently by the means that is most rapid.

If the pressure be due to a polypus, extract it; if to a deflected septum, remove the deflection; and if it be, as is most likely the case, due to an hypertrophy, reduce it with the galvano-cautery, the snare, glacial acetic acid, or chromic acid. I find myself most frequently resorting to the latter. After the removal of the pressure, pain ceases to a great extent, if not entirely; then the more soothing treatment of vaseline sprays, in combination with cocaine, pinus canadensis, oil of terebene, or oil of eucalyptus, daily or tri-weekly, will complete the resolution.

Many cases that are essentially acute, due to a recurrent attack of an old hypertrophy, may be relieved by a few well-applied cocaine sprays; but, if left in this condition, the patient will be subject to a recurrent attack at the next coryza.

I will amplify only a few cases from my note-book. Mr. H——, about thirty years of age, commercial traveller, came to me with excruciating pains in his forehead, temples, across the bridge of his nose, and over the cheek-bones of the left side; had been subject to these attacks for three years, each time he caught cold; had had no relief from medication except when insensible from morphine; attacks lasted from three to ten days. Upon examination, both nasal passages were found closed from acute coryza. After opening the passages, by inserting cocaine on a cotton probe, sufficiently to introduce a spray of cocaine and vaseline, relief followed almost instantly. He was then instructed to use cocaine in a vaseline spray during the remainder of the afternoon and evening as often as was necessary to keep the passages open. He returned the next morning, having had but slight recurrences of pain during the interim. At this treatment, after thoroughly opening the passages with cocaine in a vaseline spray, I touched the more prominent hypertrophies lightly with glacial acetic acid and ordered the continuance of his spray at less frequent intervals. At his return the following day he reported himself entirely free from neuralgia, and when I had thoroughly removed the acid sloughs, the nasal passages were comparatively open. The patient left town that day, without pursuing the treatment as I advised. Three months afterward he felt an attack coming on in a neighboring city, when he started at once to me. After giving him relief as before, he consented to remain three weeks, during which time I treated him in the conventional way for nasal hypertrophy. In writing to me two weeks afterward, he said he had never had a recurrence of his attacks. I find in my note-book fifteen other cases similar in most respects to this one; some of them evinced some mild asthmatic symptoms, in addition to the facial and brow pains.

The same treatment was effectual in all of these cases, without an exception.

I will now describe a case more chronic in its nature.

Mr. W——, aged thirty-two, gave me his history as follows: About six months previous to his first visit to me he began having severe attacks of neuralgia in his face and forehead, when shortly afterward the pains became almost constant, and he had asthmatic symptoms at night; he was oppressed by a feeling of malaise; lost his appetite and strength, and his weight decreased from two hundred and ten to one hundred and thirty pounds in a few months. After exhausting the skill of his family physician he went for six months to a hydropathic institution, thence to another sanatorium for two months more. In the meantime he had taken many anti-neuralgic and tonic remedies. When I first saw him the pains in the forehead, temples, across the bridge of the nose, and over the left malar bone were almost constant; he had nightly attacks of asthma in a mild form, but sufficient to interfere with his rest; he had a haggard complexion, was weak, and weighed only one hundred and thirty pounds. Upon examining his nasal cavity I found a septum deflection on the left side and a large turbinated hypertrophy just opposite. In addition to this, a posterior nasal examination revealed a large polypus which completely occluded the left chonæ; the right side was also in a hypertrophic condition. The right nasal passage had been almost constantly occluded for six or eight months. He said it had not been suspected before, that his nose had anything to do with his trouble. The polypus was removed with a Sajous post-nasal snare at the first sitting, when a partial opening was effected. I do not consider it wonderful when I say that he had no severe pains after the first sitting. He was instructed how to use cocaine in a vaseline spray, to prevent the recurrence of the pains. My treatments were continued at first daily, then tri-weekly, and weekly for months, until he was entirely relieved of his nasal trouble. He began to regain his strength and weight at once, and he had, at no time, anything more than a trifling recurrence of neuralgia.

It is not eighteen months since I completed his treatment; he weighs two hundred pounds, and has had no sign of neuralgia since the treatment ceased.

I find in my notes five cases similar in many respects to this one, particularly in that they were of long standing before their etiology was recognized. The nasal features of these cases were not the same, except that pressure existed in all.

I will describe a case to show that both nasal pressure and refractive error may be the combined cause of these reflex neuralgias. Mrs. R——, aged thirty-six, came to me with the symptoms described above, together with nausea and dizziness after having made the slightest attempt to read or to do any close work. I first thought I had a case of refractive error plain and simple; so I paralyzed the accommodation and corrected the astigmatism, which was moderate in degree. She was greatly relieved, to the extent that she had no nausea and dizziness after reading, which act she performed better than ever before. There seemed, however, to be but little, if any, relief from her forehead and facial neuralgia, which continued to nag her at intervals. After ten days I examined the nasal cavity, which I had failed to do before, when I found a decided hypertrophy over the turbinated bones of both sides. Not until this was removed, after a treatment of six weeks, was she entirely relieved of all her symptoms. While at a summer-resort during the following summer she broke her glasses, and in trying to do without them she had a slight return of browache, and when she tried to read, a tendency to nausea and dizziness followed. After receiving her new glasses there was no return of any of her symptoms. I find in my notes three other cases similar in many particulars to this one.

I know of no class of cases that apply to us for relief

in which treatment can give more prompt and satisfactory results; indeed, when we make no mistake in the etiology the result is absolutely sure, if we resort to means that are effectual in removing the pressure upon the terminal sensitive nerves that are distributed to the nasal mucous membrane.

## Clinical Department.

### A CLINICAL NOTE ON CHLOROFORM WATER.

By HARVEY B. BASHORE, M.D.,
WEST FAIRVIEW, PA.

Chloroform water has lately proved to be of much value to me in the treatment of false croup, and is in this affection superior, I think, to chloral, in that it is not so dangerous and is eliminated in part by the lungs; of course, its action is purely local and its value, too, probably due to the sedative effect upon the sensitive filaments of the superior laryngeal nerve.

I use a solution consisting of five to ten minims of chloroform to an ounce of water, to which is added a little glycerine to aid the solubility of the chloroform. A teaspoonful of this is given every half-hour during an attack, and if there is any dyspnœa the following day, a teaspoonful is given every two hours, increased in frequency to every hour during the evening.

This method of treatment—which is especially applicable to those cases in which the dyspnœa and cough continue during the day—I have used very successfully.

### CONGENITAL ABSENCE OF RIGHT TESTIS—ECTOPIA OF LEFT—OPERATION FOR ECTOPIA—RECOVERY.

By HAMILTON WILLIAMS, M.D.,
BROOKLYN, N. Y.

Mr. ——, of Brooklyn, aged twenty-three, consulted me early in September last. He complained of a tumor in the left groin, which, of recent years, had troubled him very much, interfering, by reason of attendant pain, with locomotion, and with the discharge of the sufficiently laborious duties of his calling. The upper limit of the tumor reached to within a few lines of the level of the external abdominal ring, while its inner border was distant somewhat more than an inch from the line of descent of the cord. The size was that of a pigeon's egg. Some pressure was necessary to elicit pain, and then it was hardly of the sickening testicular type, though, indeed, the latter had a rather awkward knack of "materializing" when the patient walked much or lifted weights. There was no moving of the tumor *from* its bed, but *in* it there was a possibility of some slight axial rotation. The scrotum was empty on both sides, and of no more than two-thirds normal size. The diagnosis was that of ectopia of the left testis. No trace was to be found of the right. The patient attributed his condition to a fall when about twelve years of age, but the absence of cicatricial marks and the testimony of his mother attested its congenital origin. He was otherwise well built, and might have been deemed robust, were it not for extreme nervous debility, hesitating, faltering manner, and unfixed gaze. He was much depressed from a prolonged experience of "wet dreams," "spermatorrhœa," want of "courage" in the society of women, and the dismal categories of the advertising quacks. I operated on September 17th. An incision was made over the tumor. The coverings were precisely those of the testicle within the scrotum, save that the superficial fascia of the groin answered for the dartos. On passing through the parietal layer of the tunica vaginalis, the gland was easily lifted from its bed, but extensive adhesions, some possibly inflammatory in origin, stood in the way of its traction in the direction of the scrotum. The adhesions were torn through without avail, and I began to fear the cord would prove too short for the journey. An upward and inward extension of the incision revealed a looping of the cord between the globus major and the external abdominal ring. Further adhesions extending into the canal maintained this looped condition. The cord, straightened out by the severance of the adhesions, gained sufficiently in length, but with none to spare. It was evident that others affected it within the ring. An incision was now made from near the lower extremity of the former downward and inward to the scrotum and along its side, yet somewhat posteriorly. The inner side of the pocket formed by the parietal layer of the tunica vaginalis was next freely torn through. This had hitherto, after the manner of a partition wall, stood across the road to the scrotum. The removal of the gland with an intact parietal covering would have necessitated overmuch dissection to no useful purpose. The testicle was now placed on the scrotum, and retained in position by sutures attaching its lower end to the base near the septum. Having closed the wound, I put a second line of sutures through the scrotum, so as to confine closely the testicle between them and the septum. That I found to answer well. All was done under the strictest antisepsis. There was absolutely no suppuration, and even the precaution was not taken of providing for drainage in the dependent portion of the wound. He made a perfect recovery, being out in ten days. Every symptom and consequence of perverted functional activity of the gland left ahead of the sutures. The constraint of the gland, in its irregular site, brought about all the nerve trouble with advancing manhood. Even from the artistic stand-point of the nude and antique, he is a much more available Apollo. He himself spoke of "being a man at last." In conclusion, it may be noted that a firm band of fibres, shooting from the extremity of the testis on toward the perinæum, and attached probably to some portion of the pubic arch, perhaps as far back as the ischial tuberosity, showed the anomaly to spring from an irregular origin of the gubernacular cord.

### URÆMIC CONVULSIONS CONTROLLED BY MORPHINE.

Dr. F. J. Bowles, of New York City, reports the following case: "On October 7th, C. D——, aged thirteen, gave the ordinary symptoms of malarial poisoning. When seen on the 28th, for a cold, she had improved, although headaches were still complained of. On the same day her mother came with her and called my attention to an abdominal distention and a slight puffiness about the eyes, saying, as she did so, that she believed these conditions, together with headaches and an irritability of disposition, had been present for the past few months. Some of these symptoms were thought to be the result of the bad drainage, ventilation, etc., of the school house where she was attending school.

"Upon the addition of nitric acid to the urine, albumin was precipitated to the extent of one-half the column. I would mention in this connection, as having a possible bearing on the cause, a habit our patient had acquired at a very early age of retaining her urine, until obliged by discomfort to void it. It was not an uncommon thing for her to retain the urine after retiring at night, until her return from school, on the afternoon of the following day.

"After discovering albumin on the 28th, I adopted measures for increasing the activity of the skin, bowels, and kidneys. In this I was partially successful, until the night of October 7th, when there was total suppression, with uræmic convulsions. Impressed with the gravity of the case, I called in Dr. Sumner A. Mason, when further efforts in the same direction were made. Between the hours of twelve at midnight on the 7th, and four in the afternoon of the 8th, she had twelve convulsions. At

that hour I called and found her in the last of a series of three. The pulse was uncountable, respiration shallow and irregular, and the general condition such as to point to a speedy dissolution.

"Believing that the means employed to bring about an action of the kidneys had been interfered with by the convulsive seizures, it occurred to me that if I could procure perfect relaxation an action might yet be secured. To this end I gave a hypodermic injection of morphia sulphate guarded by atropia sulphate. The effect was all that could be looked for. The convulsions were arrested, the pulse came down to ninety, respiration became uniform and tranquil, and a quiet sleep ensued. In a few moments I was gratified to find there had been a copious flow of urine. The recovery from that time to the present has been uninterrupted. The albumin, which very nearly filled the column, has totally disappeared under appropriate treatment.

"What impressed me as being of special interest in this case, and which led me to report it, were the importance of examining the urine of patients with headaches, and the value of morphine given at the right time."

## Progress of Medical Science.

THE ACIDS OF THE STOMACH.—There is no doubt that the chief acid found in the stomach during natural digestion is free hydrochloric acid. This has been abundantly proved by Bidder and Schmidt, and numerous observers succeeding them (*The British Medical Journal*). The methods used are, however, too long and too complicated to employ in clinical work. The physician wishes to know what, in a particular case of disease, are the chemical changes going on in the stomach: whether, for example, hydrochloric acid is present as well as pepsin and organic acids. Now, in the examination of the contents of a diseased stomach three forms of acid may be present—hydrochloric acid, a mineral acid; organic acids, such as lactic acid, butyric, etc.; and thirdly, acid phosphates. It is chiefly of importance to determine the presence of hydrochloric acid and of organic acids. Many methods have been proposed for doing this; they consist mainly in testing the effect of the stomach contents on various colored solutions. Thus a solution of methyl-violet is decolorized by hydrochloric acid, so that if this reaction is obtained the free acid is present in the liquid tested. Lactic acid turns the violet a dirty yellow. Tropæolin also is turned deep reddish-brown by free hydrochloric acid. Unfortunately these tests, simple as they appear, are not accurate, since the reactions are interfered with by the presence of peptones and of some neutral salts, and, as these are usually present in the stomach contents, no reliable results can be obtained by using methyl-violet and tropæolin. They have been superseded by congo-red, which is turned blue by free hydrochloric acid, and by a solution of vanillin and phloroglucin in alcohol, which is turned a deep red by the same acid. These simple clinical tests are, however, rendered useless by the fact that they are interfered with by the presence of peptone, ammonium salts, chlorides, and phosphates. In the present state of our knowledge, therefore, there is no reliable indicator for the presence of free hydrochloric acid in the stomach contents. Other methods which may be used are too complicated for clinical use. Thus ether has the property of dissolving organic acids from a liquid, leaving the mineral acids in solution. It may thus be used for separating the lactic, butyric, and other acids from the hydrochloric acid; and if, in a liquid obtained from the stomach, it is found that ether removes the whole of the acids present, it may be concluded that no free hydrochloric acid is present. In many cases this conclusion would be an important one as a clear indication for a line of treatment. Dr. Leo has lately published a new method for the indication of free hydrochloric acid which may prove useful. Leo considers the case where it is only a question of the presence of free hydric chloride and of an acid phosphate. To a few drops of the stomach contents a pinch of carbonate of calcium is added; if the acidity, as tested by litmus paper, disappears, only a free acid is present, but if the liquid is still acid after the addition of the chalk, an acid salt is present. If, moreover, organic acids be present they must be first removed by shaking with ether before the chalk is added. It does not seem that Leo's method is one that can be applied at the bedside, because the detection of free hydrochloric acid is chiefly requisite in those cases in which organic acids are also present, as in cases of dilated stomach. At present, indeed, a ready method, suitable in clinical practice for the detection of free hydrochloric acid in organic liquids, is a desideratum.

THE PSYCHO-MOTOR ORIGIN OF DELIRIUM.—M. Ritti, of Charenton, read a paper recently on the psycho-motor origin of delirium, in the name of a colleague. As those of language, the troubles of the intellect should be attributed to sensorial and motor lesions; there is no form of mental disease in which these latter are more manifest than that of mania (*The Medical Press*). It is by depression of the psycho-motor energy that the patient feels himself isolated from the outside world, and by its animation in the state of excitability, irritability, that ideas of greatness, strength, etc., seize the individual. In the discussion which followed, M. Gamier said that, although he agreed in part with what had been read, he could not help remarking that in general paralysis or softening of the brain, in second and third period, ideas of grandeur, etc., attain their maximum, although the motor power is diminished to its lowest ebb. M. Regis spoke on four cases of hypocardriacal lypemania, and gave the distinct signs of lypemania and softening of the brain, which he enumerated as follows: The delirium of softening of the brain presents a character of absurdity, stupidity, and incoherence. It appears suddenly, is mobile and inconsistent, the patients speak without conviction and do not contradict, and are slow to speak on their sufferings, while the reverse obtains in lypemania. The patient discourses constantly on his affection, seeks to convince those around him, and gets angry when contradicted. In softening of the brain, the delirium takes sometimes the form of greatness, ambition, etc., but nothing of that sort is witnessed in lypemania. The delirium of softening of the brain is not benefited by morphia, as in the case of the other form. The former comes on between the ages of thirty-five and forty-five, while lypemania is observed at a more advanced age, and more frequently in women than men in the ratio of eight to twelve; ideas of self-destruction, voluntary mutilation, apprehension of not being able to die, etc., are frequent, but for many years the intellect remains intact and the mind lucid. The examination of the viscera gives generally a negative result, but a saburral state of the tongue, inertia of the stomach, constipation, a frequent pulse, and progressive wasting is often witnessed. A cure is possible.

THE TREATMENT OF INGROWING NAIL WITH TIN FOIL.—Dr. Theodore Clemens recommends the following treatment: After thoroughly cleansing the diseased parts with soap and water, and then drying, the edges of the nail are covered with one or two layers of tin-foil. The strips of tin-foil are held in position by a thin layer of yellow wax, care being taken to place the strips on all places where the nail is in contact with the flesh. This packing need only be renewed two or three times during the first few weeks, the procedure being simple, painless, and easily carried out by the patient.—*International Journal of Surgery.*

CHOLERA IN PERSIA.—A correspondent of the *Bulletin Medical*, writing from Teheran, says that cholera in a virulent form exists throughout the valley of the Euphrates, and it is feared that it will become epidemic in Persia.

# THE MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

**New York, December 7, 1889.**

## THE ABOLITION OF THE TITLE OF DOCTOR.

COUNTING the druggists, corn-doctors, horse-doctors, dentists, chemists, clergymen, and philosophers, the number of persons not physicians who receive and are addressed by the title of doctor (or "doc") must nearly or quite equal that of the medical profession.

The title is therefore not a distinguishing one, nor does it carry with it any especial respect, call forth any peculiar deference, or add ordinarily to one's social advantages. The number of "docs" and doctors in this country is enormous and burdensome. The name is sounded in the ear at every corner, and in every form or kind of gathering. The citizen goes to Dr. A for his preaching, to Dr. B for his teeth, to Dr. C for his horse, and to Dr. D for his corns, while his wife goes to Dr. E for her nails and to Dr. F for her malaria; and the result is that the average family of modern New York lives in a delirium of "docs" and doctors, who are continually engaged in the patchwork of the body or soul.

The question occasionally arises, and is seriously discussed, whether it is not time for self-respecting physicians to consider the propriety of dropping the title of "doctor" in their intercourse with their fellows altogether, and leave it to the dentists, the veterinarians, and philosophers. This title is not used by English surgeons, and they seem to be not the worse in reputation or less skilful and successful in practice.

There was a time when a special title, a peculiar costume, and an affected air and deportment were essential to the physician. Without their "cassocks and mules, they could not have duped the world," said Pascal. Now people are beginning to depend on physicians because they have learning and experience and skill; not because of their deportment or pretensions. We say they are beginning to do so; and we are forced to confess that it is only a beginning.

But the magic of the name of "doctor" has long gone; it is as non-distinctive, weak, and effacive as that of a "colonel" in Kentucky, or a "corporal" in Hayti. It simply identifies a man in a crowd as being one of two hundred thousand "docs" and doctors who are diffused through the land.

The time will come, and is coming, when medical men will be glad to stand on the same plane as other professions and classes, and be before the world plain "Mr.," a title which is considered good enough for the President of the United States.

Some day there will be founded, we trust, a Society for the Abolition of the Title of Doctor, and of the slavery of learned gentlemen to that most noxious of invocatives, "Doc."

## THE GARTER AND VARICOSE VEINS.

JUST as the garter has begun again to become an *objet de luxe* and to receive the thought and inspiration of artistic minds, the sanitarian has put his foot down and said that the garter is a source of disease. By constricting the limb it impedes the flow of venous blood and leads to the production of varicose veins, œdematous ankles, and other morbid conditions. Such has been the view taken at a recent discussion of the subject by English physicians. We fancy that the garter, like many others of the things of this life, may be a thing of beauty, or of evil; it may adorn loveliness, circumscribe angelic outlines, and support comfortably and artistically and healthfully the superior circumference of knit goods; or it may constrict, asphyxiate, and puff up sound and symmetrical limbs into varicose and variegated ugliness. Those who have seen dispensary service can recall the heavy Irish ladies who sit down and laboriously untie the tight string or dirty rag which holds up the stocking, and expose the varicose ulcer, rich in excretions and blushing phlegmonously over its state. This represents, no doubt, the worst phase of the garter, and the class of cases in which it may do harm.

But, as a rule, the garter is a source of no disease. Varicose veins occur oftener in men than in women, and proportionately oftener in athletes and men trained to severe exertion. There are many things, indeed, which cause them, and artificial constriction of the limbs seems to be a very remote and rare factor. In England we are told that the demand for "anti-varicose" stockings is chiefly made by full-fed men who lead sedentary lives and drink more wine than is good for them. A wearer of the anti-varicose stocking feels worse after a series of dinner-parties, when the tempting varieties of the *menu* lead him to indulge too freely in the pleasures of the palate.

Obviously, no very bad case can be made out against the garter, provided it is a good garter, combining the maximum of support with the minimun of constriction, blending harmoniously with the hosiery and the circulation. The garter has come to stay; and the doctor had better prescribe a proper kind than preach its abolition.

## OUR STATE INSANE.

IT is understood that at the next meeting of the State Legislature another effort will be made to pass a law requiring all county insane, except those of New York and Kings, to be sent to State institutions.

The care of pauper insane by the counties, though much better than it used to be, is still in many cases inhuman and disgraceful.

In most of the poor-houses where the unfortunates are kept the expense averages but twenty cents a day, while in one county it has been reduced to eighteen cents.

The plan of transporting the insane to large and properly equipped hospitals, under the care of experienced medical officers, is endorsed by all who have investigated the subject impartially, and is only opposed by a clique of

politicians who use the county institutions as "spoils," and desire to make as much out of them as possible.

It would be more just and wise, and eventually more economical, to erect such new State asylums as might be needed, and have the pauper insane of the counties transferred to them.

The only objection to this plan that can be made is that there would be waste and extravagance in putting up these new buildings. This is unfortunately a valid objection, but not by any means an insurmountable one.

### AT IT AGAIN.

OUR talented townsman, Dr. W. P. Northrup, appears again in the rôle of contributor to *Scribner's*. In the Christmas number just issued is an interesting and graphically told story of the habits and religious customs of the Bretons. The pardon of Ste. Anne d'Auray is the suggestive title to the sketches, which are handled with rare skill and judgment. The conception centred upon a summer vacation in Brittany and a psychological study of a very curious people. It is well worth reading. It shows how a medical man can spend his vacation with pleasure to himself and profit to his readers.

### SPECIAL HOSPITALS FOR PHTHISIS.

THE recognition of the contagiousness of phthisis, and of the importance of prophylaxis in connection with this disease, has given rise to an active discussion regarding the advisability of having separate hospitals for phthisical patients. The matter is being agitated especially in Berlin, and, no doubt, there will soon be some practical outcome. It is desirable not to alarm unduly the public on this matter; for phthisis is not very contagious and is, indeed, practically non-transmissible to those who have not the proper soil. But it would be advisable, for many reasons outside the contagiousness of the disease, to have these special hospitals. The treatment of phthisis, if properly carried out, requires much attention and skill, and the employment often of special apparatus.

Such special treatment could be much better given if the cases were placed together, either in a single hospital or separate wards. City hospitals, in particular, could deal better with phthisis if they had country branches to which curable cases could be sent.

### HEIGHT AND WEIGHT IN THEIR RELATION TO HEALTH.

THE body weight of adult men ranges from 60 to 70 kilogrammes, according to Quetelet. Krause gives a mean of 64 kilos., Beneke, of 63.074, and Busch, of 65.1. For women the range is 52 to 56; and the mean for men according to Vierordt is 65, for women 55, kilos. The average height of young American students of the age of twenty-three years, as determined by measurements of Dr. H. Gihon, is 172 centimetres (68.+ inches).

The weight at this age was 61.2 kilos. (140 lbs.), while the weight at this age, as determined by Quetelet, was 64.5 for men and 55.2 for women.

Bernhardt established the following formula: Assuming H to equal the body height, C the circumference of the chest at the mammary line, and W the body weight, then for an average constitution $W = \frac{H \times C}{2 \cdot 4 \cdot 0}$. When the denominator falls to 209.76, the individual has a feeble constitution; when it reaches 256.8, it indicates a very robust constitution.

It has also been determined that there is a relation between body weight and height which undergoes certain definite laws. The weight reaches its greatest amount at about the fortieth year, and then sinks as old age comes on.

The greatest height is reached at the age of about thirty; then there is a slight decrease, which in old age may amount to 6 or 7 centimetres.

The height and weight of man are, according to Quetelet,

| At | Height. | Weight. |
|---|---|---|
| 30th year | 172.2 | 68.90 |
| 40th " | 171.3 | 68.81 |
| 50th " | 167.4 | 67.45 |
| 60th " | 163.9 | 65.50 |
| 70th " | 162.3 | 63.03 |

We give the foregoing figures in connection with some recent observations upon weight, height, and disease made by Dr. J. Foster Bush, medical examiner for the American Legion of Honor. In his report for the years 1887 to 1889 he analyzes the mortality statistics of that period, including 1,464 deaths. He gives tables showing the height, weight, and cause of death. He finds that in phthisis, cancer, apoplexy, and renal disease, there was a very large proportion above or below the average of weight to height, and that not more than two or three per cent. hit the mean. In apoplexy, cancer, cardiac, and renal diseases, the greater number were above the average of weight to height; in phthisis the greater number were below.

Gihon's tables show that in a given number of healthy young men about one-fourth are of mean height and weight, while about five per cent. are above or below what is taken as a normal range.

The figures given by Dr. Bush are not of very great value, for he does not state how much above or below the average his cases were, and it is admitted that there is a normal range. They do call attention, however, to the fact that a wide departure from a normal average in the mean height and weight indicates, as a rule, a defective constitution. Physicians would do well, therefore, to make themselves familiar with the physical measurements of their patients.

According to Gihon's table, the height of students at twenty-three is 172 ctm. (66 in.), the weight 63.5 kilos. (140 lbs.)

The mean height of 1,486,039 adults, mostly recruits and soldiers, was 172.08 kilos. (67.75 in.); the average weight of 32,584 adults was 64.55 kilos. (142.30 lbs.); the average chest-girth 87.68 ctm. (34.52 in.). This would indicate for the American constitution, according to Bernhardt's formula, the following:

$$64.55 = \frac{172.08 \times 87.6}{2\,3\,4}$$

which places the male constitution of this country rather below par average.

A NURSE DIES BY AN ETHER EXPLOSION.—At a private hospital in this city, conducted by Dr. W. Tod Helmuth, a nurse lost her life by an explosion of sulphuric ether. She was in the act of pouring ether from one bottle to another, and is supposed to have been too near to a gas-light. Fatal burns were the result of the accident, followed by death about forty-eight hours later.

## News of the Week.

Dr. Florence O. Donohue, of Syracuse, N. Y., who was recently appointed a member of the local Board of Health by Mayor Kirk, received yesterday a commission naming him a member of the State Board of Health.

Trephining for General Paralysis.—Dr. T. Claye Shaw reports a case of advanced general paralysis, in which all the mental symptoms disappeared after trephining and opening the dura mater.—*British Medical Journal.*

England Contributes to the Pasteur Institute.—At a meeting of the Pasteur Institute Fund, held in London recently, it was unanimously resolved to transmit to M. Pasteur the sum of 40,000 frs., on behalf of the Institute, as a grateful acknowledgment of the services rendered by him to English patients.

Cincinnati has a new hospital, called Christ's Hospital.

An Epidemic of Influenza in Russia.—The daily papers announce that St. Petersburg is suffering from a curious epidemic of influenza. Practically everybody, from palaces to the lowest hovels, catches this disease, which lasts three or four days and causes great annoyance. Over forty thousand cases have already been medically reported in St. Petersburg alone, with the result that many mills and factories have had to close, and it is difficult to get cabs on the streets. The malady is now reported as appearing in Moscow and in far Siberia, and everybody is depressed over the unaccountable thing.

Cremation in Paris.—The cremation furnace in Père-la-Chaise Cemetery, in Paris, is now complete, and the Prefect of the Seine has approved the scale of charge to be enforced thereat. The charge for the use of the cremation furnace is to be 50 francs, which sum includes the keeping in the columbarium of the funeral urn containing the ashes for a period of five years.

Shocking Death of a Vienna Physician.—Quite a gloom has been cast over Vienna medical circles by the death of a young pathologist in the General Hospital here. Two months ago a patient died in the hospital of glanders caught from a horse, and Drs. Rowalski and Hoffmann subjected the body to experimental observations.. The bacillus of glanders was readily discovered, reared, and its behavior closely watched. The animals injected with it died of the horrible malady. During these observations Dr. Hoffmann caught cold and felt acute pains in his side, to allay which he injected morphia. He did this with the syringe he had used during the glanders experiments. Although it had been disinfected, some particles of the poison must have still been in it, for Dr. Hoffmann grew worse every day, and last week he succumbed in horrible agony, his body being covered with ulcers, which, when examined, proved to be filled with the glanders poison.—*Medical Press.*

Professional Cards in Newspapers.—The *Southern California Practitioner* says: "The convenience of having one's professional card in the daily paper cannot be denied; it enables the regular patients to tell when they may find you at your office. It informs them of the number of your telephone, both at office and residence; and the column also furnishes an index of practising physicians for the stranger. But a great deal of unfairness is connected with the present system. In this city, at least, the daily papers have no classification; regulars, homœopaths, and quacks all come in the same list. It would be a very easy matter, by referring to the official register, to put the legal regular physicians under one heading, the legal homœopaths and legal eclectics either before or after the regulars, and then illegal practitioners in a place by themselves. As it is now it is a game in which only the honest doctors lose; the barnacles of all the 'pathies hope to gain custom by sandwiching their cards in among those of the legal physicians. We suggest as a cure that regular physicians cease to advertise in the daily press."

Threatened Strike among Medical Men.—It is not often we are troubled with a threatened "strike" in the medical profession, but from the feeling present among the district medical officers of Moravia and Bohemia such a phenomenon is imminent, as they consider the fees and salaries, as well as the present stringency of the sanitary laws, inadequate and intolerable. Petitions signed by every medical officer have been forwarded to the provincial diets praying for redress. The result is awaited with much anxiety and suspense.—*Medical Press.*

Albuminous Food in Bright's Disease.—Senator and Semmola have both agreed that albuminous food should not be given to invalids suffering from Bright's disease. Dr. Schreiber has been devoting his attention to this subject experimentally, and now concludes that a rich diet of white of egg, raw, mixed with other nitrogenous food stuffs, has no effect on the urine either in the healthy subject or the one afflicted with Bright's disease. On the contrary, he finds that when the albumin is given in solid form it checks the amount of albumin secreted in Bright's disease. He quotes two cases of Leyden's in support of this view, as well as a case of Semmola's, where albuminous diet was prescribed and *no* increase of the albuminous secretion was observed.

Parisian Physicians on Show.—An American surgeon, visiting the Parisian hospitals, writes: "The fact that hospitals have their clinics and shows at eight or nine o'clock in the morning makes the effort to attend bad for lazy people. Fortunately I am located near that model of hospital structure, the new Hôtel-Dieu, and most of my sight-seeing has been there. R——, the crack surgeon, is getting old, and shows much shining pate. I never saw a man examine a case more thoroughly. Jolly little K——, him of speculum fame, I believe, handles women in a way that would excite execration at home, and which I can't believe is proper anywhere. To expose women from their feet to their breasts, without the comforting pretence of a sheet, and to punch their abdomens as if he were going to dig the uteri out through the walls, is not the way to make the examination chair a joy and delight. I saw one young woman of some personal attractions, and who seemed to have some modesty left, although she was a low-class Frenchwoman, tremble as if in ague during the ordeal, and shriek with pain when he forced his very short forefinger up to the cervix as if he intended to carry all before him."

THE TWENTIETH ANNIVERSARY OF THE NORTHWESTERN MEDICAL AND SURGICAL SOCIETY was celebrated by a large reception of ladies and gentlemen, on Wednesday evening, November 27th, at the house of Dr. T. H. Burchard, No. 7 East Forty-eighth Street. About one hundred guests accepted the invitation of the Society, among whom were lawyers, clergymen, and physicians with their wives. A fine musical programme was rendered by well-known artists, and by members of the Society. The guests were received by the officers and their wives. Such social episodes vary the monotony of scientific work in a medical society; and when properly managed these gatherings bespeak a healthy life and tone to medical bodies. The officers of this Society are: President, Dr. A. M. Jacobus; Vice-President, Dr. S. Baruch; Secretary, Dr. E. S. Peck.

DIAGNOSTIC VALUE OF THE SALOL TEST IN MOTOR INSUFFICIENCY OF THE STOMACH.—We recently referred to this test as being one of value in determining the motor activity of the stomach and the absorptive power of the intestines. Dr. J. Decker, of Münich, now comes forward (*Berlin Klin. Woch.*) and denies its value. From his clinical tests he finds that in healthy stomachs the time of reaction may be delayed as much as in disease.

THE KING OF PORTUGAL, who recently died at the age of fifty-two, was an extremely interesting case. He had suffered from diabetes for a long time. Two years ago he developed a large lymphoma on the shoulder. Later he had symptoms of myelitis, and finally a curious skin affection, diagnosticated by Professor Neumann as multiple gangrene. Professor Neumann received a fee of $20,000 for his diagnosis. The King had eleven physicians in attendance on him at the time of his death.

THE FIRST CONGRESS OF POLISH SURGEONS was held at Cracow on October 16th and 17th, under the presidency of Professor Rydygier.

THE EIGHTH CONGRESS OF RUSSIAN NATURALISTS AND PHYSICIANS will be held at St. Petersburg from December 27, 1889, to January 7, 1890. It will consist of eleven sections, two of which are devoted to "scientific medicine" and "scientific hygiene," respectively.

SACCHARIN.—The importation of saccharin has been for some time forbidden by France, Spain, and Portugal; Italy and Hungary have now followed the example of these countries. In Belgium a duty of 140 francs a kilogramme is levied, not only on saccharin, but on all products containing more than fifty per cent. of it. In Holland a duty of 60 florins a kilogramme will probably soon be imposed on saccharin.

"HYGIEA'S" HALF CENTURY.—Our esteemed contemporary *Hygiea*, of Stockholm, celebrates the completion of its first half-century in a magnificent number of nearly six hundred pages, containing eighteen papers in Swedish, French, and German, many of them illustrated by fine lithographic plates. The journal was founded in 1839, the first number having appeared in April of that year. The secret of our contemporary's success and long life is revealed in the frontispiece, wherein are presented the portraits of the editors in chief of the journal since its foundation. We congratulate *Hygiea*, and wish it many more semi-centennials.

# Obituary.

## PROFESSOR RICHARD VON VOLKMANN,

HALLE, GERMANY.

RICHARD VON VOLKMANN was born August 17, 1830, at Leipsic, where his father, Alfred William Volkmann, was Professor of Physiology. From Leipsic Professor Volkmann went to Dorpat, but returned in 1843 to Germany, and became Professor of Physiology at Halle. In 1850 Richard commenced the study of medicine at Halle, went afterward to Giessen, and finished his studies at Berlin under the celebrated surgeon von Langenbeck. In 1857 he settled at Halle and became an assistant in the Surgical Clinic under Professor Blasius. After the death of that surgeon, he became (1867) Professor of Surgery and Director of the Surgical Klinik, which positions he held at the time of his death.

In 1866 he served as surgeon in the Prussian Army, in the war with Austria, and in 1870–71, in the war with France, he was Surgeon-General of the Fourth Corps d'Armée. During this campaign, in his leisure hours of camp-life, he wrote his celebrated "Reveries at French Hearths," under the *nom de plume* Richard Leander, and these musings of the great surgeon will always occupy a prominent place among the works of German poets.

Volkmann introduced Lister's antisepsis in Germany, and followed it in all its details with excellent results; he was an indefatigable worker with the knife and the pen, and his name will always shine as a brilliant star among the surgeons of all nations. His "Beiträge zur Chirurgie" belong to the classical medical literature. Since 1870 he published "Sammlung Klinischer Vorträge." He is the author of numerous monographs on surgical subjects, and was engaged at the time of his death writing a monograph on carcinoma. His investigations of diseases of joints have thrown new light on this subject, and there is probably no better authority on "tuberculosis" than he was.

On Langenbeck's retirement the chair of surgery at Berlin was offered to Volkmann, but he preferred to remain at Halle, where he died on December 1st.

In recognition of his eminent services, Emperor William bestowed in 1885 the rank of a nobleman on Volkmann. Although broken down in health for several years, his death was rather unexpected.

## WALTER DE FOREST DAY, M.D.,

NEW YORK.

DR. WALTER DE FOREST DAY, for many years Sanitary Superintendent of the Board of Health, died at his residence, in this city, on November 27th. Although he had been suffering from an incurable illness since May last, his death was sudden. Dr. Day was born, in 1835, in Catskill, N. Y. He was graduated from Williams College in 1859, and soon after began the study of medicine in this city, under the late Dr. Willard Parker. He was graduated in medicine from the College of Physicians and Surgeons in 1863, but two years earlier he entered the military service of the United States as a medical cadet, and immediately after the battle of Bull Run converted the Methodist church in Alexandria, Va., into a hospital for the treatment of the wounded.

The efficiency with which he did this work gained for him the task of organizing the hospital service for the Army of the Potomac. The proficiency he displayed in this field attracted the attention of Professor Charles F. Chandler, who, when he was made President of the Board of Health of this city in 1873, selected Dr. Day as the best-equipped man for Sanitary Superintendent. He filled the Chair of Materia Medica and Botany in the College of Pharmacy for twenty-one years, and was for ten years clinical assistant to the Professor of the Practice of Medicine of the College of Physicians and Surgeons. He was also connected, from time to time, with various hospitals and dispensaries, and a member of several medical societies.

# Society Reports.

## SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

*Secona Annual Meeting, held in Nashville, Tenn., November 12, 13, and 14, 1889.*

(Continued from p. 613.)

SECOND DAY, WEDNESDAY, NOVEMBER 13TH — AFTERNOON SESSION.

THE papers of Drs. Davis and Brockaw were discussed by Drs. W. O. Roberts, Virgil O. Hardon, B. E. Hadra, A. M. Owen, Hunter McGuire, W. W. Potter, R. S. Cunningham, G. Frank Lydston, Richard Douglas, George J. Engelmann, W. E. B. Davis, and discussion closed by the essayists.

DR. B. E. HADRA, of Galveston, Tenn., read a paper entitled

### THE OPEN ABDOMINAL TREATMENT,

in which he said that abdominal surgery, notwithstanding its immense progress, has not as yet given even a moderate degree of satisfaction in acute diffuse septic peritonitis. Chronic infectious processes offer much better prospects for surgical interference, such as tuberculosis, actinomycosis, and the recently described microbic peritonitis, of as yet unknown origin.

The points making the diffuse septic peritonitis are: 1. The extensive area of peritoneal surface. with its enormous power of resorption of the poisonous fluid. 2. The active secretion into the sac, and thereby furnishing cultivating fluids for the germs. 3. The ready absorption by the lymphatics of the diaphragm. 4. General distribution of the poison by intestinal peristalsis. 5. The infection of the intestinal walls from without, and the additional infection of the peritoneal cavity by transudation and immigration of germs from the inside of the bowels. 6. Distention of the bowels, increasing the pressure and resorption. 7. The impeding effect of this latter condition upon respiration, defecation, and secretion of urine, leading to systemic poisoning by retained products of oxidization. 8. In perforative cases the contamination by fecal matter; in stab and gunshot wounds by other impurities, bile, urine, etc., and, above all, contaminated blood.

The indications for treatment, besides supporting the patient's strength, relieving suffering, giving proper action to the bowels, kidneys—in short, besides the general medical treatment—are: 1. To remove the obnoxious material—germs, fecal matter, and urine. 2. To prevent its new formation or a repetition of its entrance. The sac should be kept dry to deprive the germ of its soil. The breaks have to be mended, so that the channels of contamination may not lead to the outside. 3. To prevent the bowels from distributing the poison throughout the whole cavity. 4. To counteract pressure and suction, in order to prevent resorption of the poison. 5. To prevent infection of the peritoneum and the bowel. 6. To relieve pressure, in order to avoid disintegration and paralysis of the different structures. 7. To free respiration, defecation, and urination with tympanites as developed.

DR. L. S. MCMURTRY, of Danville, Ky., read a paper on

### TWENTY CONSECUTIVE CASES OF ABDOMINAL SECTION.

The series of cases comprised the first twenty abdominal sections performed by him, and illustrated a variety of pathological conditions and diverse complications. All the cases were in private practice, and, with two exceptions, all the operations were done at the homes of the patients. Two cases were treated as private patients in a well-appointed hospital. In many cases operative treatment was only accepted after all ordinary and so-called conservative measures had been exhausted; and in several cases the operation was only accepted when the patient's condition was regarded hopeless by physician and family. In no case, however desperate or complicated, was an operation refused. In the twenty cases there were three deaths.

The difficulties attending the diagnosis of intra-abdominal disease are well illustrated. One case of tubercular peritonitis and encysted dropsy was diagnosed by four different surgeons, before he saw the patient, as ovarian cyst. The history and physical signs were characteristic of that condition. On opening the abdomen it was found to be encysted dropsy, the result of tubercular peritonitis. Evacuation and irrigation were followed by quick recovery, and, though the peritoneum was studded everywhere with miliary tubercles, and the patient now sixty-eight years of age, she remains to-day in perfect health and activity.

A case of uterine myoma (Case No. 15) was also believed to be an ovarian cyst. The tumor was very soft; it was, besides, heavily œdematous, and fluctuated distinctly. The history and general condition of the patient tallied with deceptive diagnosis. It was only when the abdomen was opened that he had realized he was to do a supravaginal hysterectomy instead of an ovariotomy. Seven of the cases recorded were ovariotomies. The cysts were in every instance large, and had, with two exceptions, been tapped several times. One was a suppurating cyst. The only death he had to record is Case No. 16, an ovarian cyst. The operation was done in a remote part of the State, and without the essentials for protection from sepsis.

Dr. McMurtry said thorough work, irrigation, and drainage, all conjoined, give the only basis of success in the cases reported. In a number of his cases he had operated in the midst of active peritonitis, with vomiting and tympanites. In this condition of affairs he had witnessed the most gratifying results from persistent and oft-repeated exhibition of calomel, dropping two or three grains on the tongue every hour until the bowels were freely moved. Increasing experience has impressed him more and more with the difficulties of abdominal work, and makes him less confident of meeting often with simple cases.

He closed his paper with a plea for earlier interference in abdominal diseases. When operations are done in good time, before emaciation and exhaustion come, and before repeated attacks of peritonitis have complicated the comparatively easy task for the surgeon, then will the surgeon's results excel even the brilliant records of the present time.

DR. RICHARD DOUGLAS, of Nashville, Tenn., read a paper entitled

### COMPLICATIONS OCCURRING IN THE CLINICAL HISTORY OF OVARIAN TUMORS.

The papers of Drs. Hadra, McMurtry, and Douglas were discussed at length by Drs. Potter, Roberts, Stone, Wathen, Engelmann, Hardon, Haggard, Lydston, Cunningham, Brownrigg, W. E. B. Davis, and discussion closed by the essayists.

---

EVENING SESSION.

DR. G. FRANK LYDSTON, of Chicago, Ill., read a paper on

### TROPHO-NEUROSIS AS A FACTOR IN THE PHENOMENA OF SYPHILIS,

in which he called attention to the relation of disturbances of the trophic function of the sympathetic nervous system, which the author claimed were the essence of all the phenomena of syphilis. He said: The relations of certain syphilitic phenomena to organic or functional disturbances of the nervous system, and particularly the sympathetic system, are manifested here and there along the whole line of morbid phenomena developed in the course of the disease. Syphilitic fever is undoubtedly dependent upon the action of a special poison upon the sympathetic nervous system. From what we know of the trophic functions of the sympathetic, we are justified in inferring that the majority

of fevers are dependent upon the action of a specific poison upon the sympathetic ganglia. The syphilitic poison may produce disturbances of the sympathetic, with perversion of tissue-metabolism and excessive production of heat. The inconstancy of the syphilitic fever is explicable upon the ground of idiosyncrasy. The syphilitic roseola has been demonstrated to be an exception to the rule that syphilitic lesions are due to a collection of proliferating cells. It is due to vaso-motor disturbance, with resulting dilatation of capillaries. This nervous disturbance is dependent upon the impression of the syphilitic poison upon the sympathetic ganglia. The accumulation of cells in the more pronounced lesions of syphilis is simply an exaggeration of the normal process of tissue-building. As is well known, such tissue-building is presided over by the filament of the sympathetic nerves.

The symmetry of the peripheral phenomena of syphilis is suggestive of some casual condition affecting the central nervous system. As an illustration of the manner in which a nerve-lesion could produce disturbed nutrition, the author mentioned herpes zoster. Some of the lesions of syphilis which are difficult of explanation upon mechanical grounds, *i.e.*, upon the theory of localized cell accumulation, are readily explicable by central or local nervous disturbance. For example, the alopecia of syphilis is similar to that which occurs in other diseases as a consequence of local and general malnutrition incidental to disturbed nervous supply—as, for instance, alopecia areata, the alopecia produced by fevers, and the alopecia produced by neuralgic affections of the head. That the nutrition of the hair is profoundly affected by nervous disturbances, is shown by the result of fright in producing blanching of the hair.

One of the principal arguments in favor of the theory that tropho-neurosis is the foundation of syphilitic processes is the peculiar action of the disease when it attacks certain parts, syphilis seemingly possessing the power of dissecting out definite portions of osseous tissue (apparently by cutting off their nutritive supply) in a manner as cleanly as it can be done by the knife. Thus the speaker has in his possession specimens of the intermaxillary bone, portions of the alveolar process of the maxilla, the palatal and nasal processes of the superior maxilla, the malar and ossæ nasi which became necrosed and were removed from cases of late syphilis. These fragments present as natural a conformation as in their healthy condition. The ordinary explanation of destruction by pressure of syphilitic exudate will not suffice in these cases. If they be observed carefully, it will be found that the first symptoms experienced by the patient are those identical to the presence of a foreign body, *i.e.*, dead bone in the tissues. If pressure were the cause of the necrosis, the death of the bone would be preceded by more or less painful swelling and inflammation.

He claimed that all of the pathological processes incidental to syphilis are due to disturbances of nutrition produced by the impression of the syphilitic poison upon the sympathetic nervous system, and that it is immaterial to the cogency of this theory whether the poison of syphilis be a microbe, bacillus, degraded cell, or chemical poison. If any attempt has been made to show that tropho-neurosis is the basis of all syphilitic phenomena, the author is not aware of it.

---

THIRD DAY, THURSDAY, NOVEMBER 14TH—MORNING SESSION.

DR. JOHN BROWNRIGG, of Columbus, Miss., read a paper on

GUNSHOT FRACTURES OF THE FEMUR,

in which he discussed the class of cases requiring amputation, and those in which a more conservative course should be pursued. He exhibited several appliances devised by himself.

DR. HUNTER MCGUIRE, of Richmond, Va., read a paper on

THE TREATMENT OF CYSTITIS IN WOMEN,

which was followed by a paper on

THE TREATMENT OF CONTRACTED BLADDER BY HOT-WATER DILATATION,

by DR. I. S. STONE, of Lincoln, Va.

During the past few years certain protracted cases of cystitis, occurring chiefly in women, have been observed by Dr. Stone, which have resisted all known forms of medical treatment, and necessitated some surgical or mechanical measure of relief.

He describes the manner of dilatation as follows: The patient is given morphia sulphas (gr. $\frac{1}{4}$), atropia sul. (gr. $\frac{1}{150}$), hypodermically. She is placed on her back on a table for convenience (although it would answer to arrange the bed with the patient thereon to suit the operator). A soft catheter is at once inserted into the bladder, and after the urine has escaped hot water (temperature 110, °F.) is thrown into the bladder, until the patient will no longer bear it. This is allowed to escape, and is measured, giving the full size of the bladder in its present condition. As the morphia gradually becomes absorbed, the patient will bear still further distention—each time perhaps one drachm may be added to the capacity of the bladder. I prefer using a rubber ball-syringe, holding two to four ounces. The pressure of the hand is safer than that of the tube or funnel, or any instrumental gauge, as the patient generally is unable to resist the tendency to strain, owing to tenesmus produced by the expansion. As each séance should continue thirty to sixty minutes, the bladder may be filled and emptied many times, and at first the operator must be well satisfied if the gain is only one or two drachms, in a bladder whose capacity is perhaps only two ounces. As the patient becomes fully under the influence of the morphia, the water may be increased in temperature to 120° or 125° F. The very best effect follows its use when at this temperature.

These papers were discussed by Drs. Lydston, Davis, Engelmann, Roberts, Brokaw, Hadra, and closed by the essayists.

DR. BEDFORD BROWN, of Alexandria, Va., read a paper entitled

REMARKS ON OBSCURE AND MINOR FORMS OF PELVIC CELLULITIS SIMULATING MALARIAL FEVER.

By referring to his note-books he found some twelve cases of pelvic cellulitis, some of a grave and others of a minor form, but all so very obscure in their manifestation of the presence of local lesion as to be well calculated to mislead, and to cause a mistaken or false diagnosis to be made of malarial fever. There was nothing in these cases to call the attention to the pelvic organs. He has in a number of instances seen these cases run their course from beginning to end without manifesting the first symptoms of local disease in the pelvis, so that the resemblance to malarial fever was very nearly complete.

DR. JOSEPH TABER JOHNSON, of Washington, D. C., presented a paper entitled

OBSERVATIONS BASED UPON AN EXPERIENCE OF SEVENTY-TWO MISCELLANEOUS ABDOMINAL SECTIONS.

Of this number 29 were for the removal of ovarian tumors varying in size from one to sixty-four pounds, 26 recoveries, and 3 deaths; 29 cases of removal of the uterine appendages, with 27 recoveries, and 2 deaths; 7 supravaginal hysterectomies for large uterine fibroids, with 3 recoveries, and 4 deaths; 1 Cæsarean section, death on the tenth day; 1 cyst of the kidney, weighing seventy-four pounds, died of exhaustion; 1 fatal case of extra-uterine pregnancy, operated on six weeks after rupture, general peritonitis, with pulse 130, temperature 103° F. for the week previous; a fatal case of general abdominal cancer; 3 exploratory incisions, all recovered. Total, 72 laparotomies, with 59 recoveries, and 13 deaths.

Of the 53 ovarian operations, the first 3 deaths were the second, third, and fifth of his series. In the last 52 ovarian operations there have been only two deaths; one of these was from tetanus occurring on the fifteenth day after operation, when everything indicated a perfect recovery. The other was an insane patient who had been four years in an insane asylum on account of nymphomania. She could not be entirely controlled, and her efforts to get out of bed set up inflammation about the abdominal sutures, causing an abscess which burst internally and caused death.

DR. JOHNSON emphasized the statement that experience in operating was nowhere so valuable as in the abdominal cavity; that the "unexpected" was so often found, that many cases would be lost if the operator was not prepared for and equal to the emergencies as they "unexpectedly" arose.

The following papers were read by title: 1. "Puerperal Eclampsia," by John Herbert Claiborne, Petersburg, Va. 2. "Laparotomy in Intestinal Obstruction," by Cornelius Kollock, A.M., M.D., Cheraw, S. C. 3. "The Causes of Frequent Failure of Relief of Reflex Symptoms after Trachelorrhaphy," by W. F. Hyer, M.D., Meridian, Miss.

The following officers were elected: *President*—Dr. George J. Engelmann, of St. Louis, Mo.; *First Vice-President*—Dr. B. E. Hadra, of Galveston, Tenn.; *Second Vice-President*—Dr. Duncan Eve, of Nashville, Tenn.; *Secretary*—Dr. W. E. B. Davis, of Birmingham, Ala.; *Treasurer*—Dr. Hardin P. Cochrane, of Birmingham, Ala.

On motion, the Association adjourned to meet in Atlanta, Ga., the second Tuesday in November, 1890.

## NEW JERSEY SANITARY ASSOCIATION.

*Fifteenth Annual Meeting, held at the State House, Trenton, N. J., November 22 and 23, 1889.*

FRIDAY, NOVEMBER 22D—FIRST DAY.

AFTER an address of welcome by Dr. Wetherill, chairman of the local Association, C. PHILLIPS BASSETT, of Newark, read a paper on the

EAST ORANGE SEWAGE-DISPOSAL WORKS

as compared with other methods. The question of sewage-disposal occupied serious attention from 1883 to 1886, as no system of sewage-application had been constructed in this country at all applicable to the conditions found in East Orange; viz., small available area of land in the midst of a dense suburban population, and a high degree of chemical purity in the effluent from the works, which had to be turned into a small stream tributary to the Passaic, close to the Newark and Jersey City water-supply intakes. No other works have been constructed in this country at all competent to meet such conditions, a claim which was confirmed in discussion by other members.

G. W. HOWELL presented a report on the

PASSAIC RIVER DRAINAGE.

The river drains an area of eight hundred and thirty-three square miles, with thirteen thousand acres liable to be overflowed for four or five days at a time, owing to the smallness of the fall of the stream. Dr. George H. Cook in his lifetime devised a system to remedy this, which is now in process of application. The Association adopted a memorial to the memory of Dr. Cook.

THE IMPROVEMENT OF SANITARY CONDITIONS IN THE HEALTH AND PLEASURE RESORTS OF NEW JERSEY

was the theme discussed by DR. HENRY MITCHELL, of Asbury Park. Dr. Mitchell says the summer-resort business of New Jersey has reached the dimensions of one of the great industries of that commonwealth, so that enlightened regard for self-interest demands the adoption of the best possible sanitary measures; yet in many cases they were entirely disregarded, as in the case of a "sanitarium" now building, with several beautiful cottages, and a hotel to cost $100,000, but without sewers or a public water-supply. He recommended increased powers of the State Board, and publication of local shortcomings, to arouse neglectful communities.

The paper on

THE CLIMATIC TREATMENT OF GASTRO-INTESTINAL DISEASES IN CHILDREN,

by DR. BOARDMAN REED, of Atlantic City, was read by Secretary English. The question why a change of air effects such striking remedial results has never been satisfactorily answered; but it is probable that there are ingredients peculiar to the atmosphere of every locality that have a tonic effect at first, but later, like too long a course of quinine, they cease to stimulate. The best treatment of graver forms of summer complaint is the preventive one, and the best prevention is removal from large cities before the hot season begins.

A paper on

THE NEED OF MEDICAL OFFICERS FOR SCHOOL-DISTRICTS

was read by DR. G. F. WILBUR, of Asbury Park. Stress was laid on purity of water-supply; on the arrangement of light for rooms; on attention to thorough personal comfort of children in position, support of limbs, etc.; on dryness of the site selected for school-buildings; on heating and ventilation of buildings, and on direction of the exercise of students. He recommended that schools be under direct and constant medical supervision.

The annual address of the President, DR. DOWLING BENJAMIN, on Friday evening, was on

THE THERMOMETRY OF HYGIENE.

He said the tendency to frequent colds and the progress of civilization is to render the human race more feeble; so that every nation which has attained a high summit of civilization has fallen into decay, and we can hardly hope to be an exception. The question, "What is a cold?" is hard to answer, but we can describe the conditions which indicate it; namely, inflammation and congestion of mucous membranes of mouth, nose, etc. He reviewed the etiology of colds, which are oftenest taken in the house, and made practical suggestions as to methods of ventilation, which should never be allowed in winter from a cold, open window. He condemned the ventilation of the State House, where they were meeting, animadverting on the misplaced foul-air registers near the ceiling, whereas they should be below. He concluded by congratulating the Association on the beneficent result to the community of their labors, notwithstanding that sanitary science is not yet generally appreciated.

JAMES M. GREEN, president of the State Normal School, read a paper on

PHYSICAL CULTURE IN ITS HYGIENIC RELATIONS.

Mind is a function of brain; its strength therefore is proportionate to development of the brain; and the symmetrical development of the brain depends on that of the body.

SATURDAY, NOVEMBER 23D—SECOND DAY.

A paper on

THE RELATION OF CONDUITS TO THE HEALTHFULNESS OF WATER

was read by DR. W. K. NEWTON, of Paterson. Discussing in detail the various materials ordinarily employed for conduits, he finds nothing to condemn except lead pipes, which are always attended with a certain degree of danger, as lead is a cumulative poison, or 1-100 grain per gallon produces characteristic symptoms, paralysis, colic, etc. He recommended abandoning the use of lead suction-pipes to wells; and condemned, as unfit to drink, water that has stood in lead-lined cisterns or in lead pipes.

Papers by PROFESSOR S. G. DIXON, of the University of Pennsylvania, on

"TUBERCULOSIS" AND "TYPHOID FEVER IN MUNICH,"

were read by Dr. Egbert. In the latter paper he said: "I know of no other civilized nation that gives so little support and encouragement to sanitary matters as does this great Republic." The example of the city of Munich, by "its liberal support of its grand old sanitary professor, Herr von Pettenkofer," was presented for imitation. From 1866 to 1880 the mortality from typhoid averaged 332 per 100,000; from 1881 to 1888, only 42. This result he attributed to Von Pettenkofer, though the water-supply had also been improved. It appeared, however, that the ratio of mortality was no greater in the portion of the city provided with the old water-supply than in that of the new supply. He believes that typhoid bacillus cannot live over four days in the average water supplied to cities, basing his belief on experiments with bacilli exposed for more than four days to Schuylkill water.

A resolution was adopted testifying to the deep loss felt by the Association in the death of ex-President J. L. Bodine.

ELECTION OF OFFICERS.

The Executive Council presented the report of the nominations of officers for the ensuing year, which was unanimously adopted, as follows:

*President*—George P. Olcott, C.E., East Orange; *First Vice-President*—Hon. E. O. Chapman, Trenton; *Second Vice-President*—E. L. B. Godfrey, M.D., Camden; *Recording Secretary*—D. C. English, M.D., New Brunswick; *Corresponding Secretary*—Professor J. Madison Watson, Elizabeth; *Treasurer*—George W. Howell, C.E., Morristown.

## Correspondence.

### MEDICAL EXAMINATIONS AND CIVIL SERVICE REFORM. CAN THESE THINGS BE?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue for November 2d, I notice the following editorial paragraph: "It is well known that the state of civil service reform in New York is not what its friends could wish it to be; and that it would be well if some clear presentment of the facts were made by those who have had occasion to know best, as to the details and as to abuses—in the interests of better sanitation. It looks as if the only answer to the question was, 'What are you going to do about it?'"

Having had personal experience in the ways of alleged Civil Service Reform and its workings as applied to New York City, I have determined, in the interest of the medical fraternity, to respond to your appeal, hoping that some ultimate good may result therefrom.

It is evident to those who have had occasion to approach the machine that there is "something rotten in Denmark." Possibly a permanent coryza may afflict the members of the Civil Service Board, and they do not observe the stench. Possibly they are incompetent, or perhaps so occupied by other and to them more important cares and duties, that their subordinates have opportunities for disreputable acts which pass unobserved.

No one, I think, questions the personal honesty of the gentlemen who compose this board. But when a battle is fought, the responsibility, on the defeated side, rests with the general in charge; and he cannot shift the load to other shoulders by complaining of a lack of efficiency or discipline in his subordinate officers. The simile holds good in the struggle between reform on the one hand, and political "pull" and "influoence" on the other. The people have reason to be thoroughly dissatisfied with the commanding officers on the side of justice. They have been laggards in the fight, and should be replaced by men who are Argus-eyed: men not alone who are conscientious, but who also will put the same energy and determination into the cause of the right as are necessary to compass and maintain the success of any great business firm.

As to the politicians—we have no just reason for complaint. As found in New York they are "statesmen" for revenue only—for the money there is in it. To a man they hate the Civil Service laws, formulated to cut away their patronage by removing appointments from their hands. And as they find many a loophole of escape, they also despise these laws and the weak supporters thereof.

We have herein no cause for complaint, as we cannot expect assistance nor anything but keen antagonism from "our friends the enemy." He would be a fool or a coward who laments because the enemy does not give him aid. But we do have just cause for indignation when we find indifference, or something worse, within our own camp.

Let me speak only whereof I know. Concerning Civil Service as applied to others than medical men, I know nothing. But in respect to physicians I have had some experience which I now propose to lay before the profession.

And here let me say that I have no axe to grind. My own days of examinations are long past. Such personal grievance as I have had has not been hastily thrust before the public, either for sympathy or for any other reason. This must be admitted without argument, since my own experience dates back nearly five years; and yet not from that day until now have I published a word regarding the matter. Nor would I do so even now except for the hope that your editorial, serving as a text and an incentive, may lead others to do likewise; and that together we may accomplish something more than one alone can do.

The first Civil Service examination for permanent positions for medical men, ever held in New York, I believe, was that of February 3 and 4, 1885. There was a vacancy in the number of Police Surgeons owing to the death of a member of this corps. The position is a desirable one, being of certain tenure, and the salary being $1,500 at first, later, $2,250 per annum; with abundant time for private practice, as the duties are generally light.

This examination was duly and properly advertised beforehand in THE MEDICAL RECORD and *The Medical Journal*; and thirty-nine physicians, of whom I was one, competed for the appointment. We were examined for the greater part of two days upon the seven main branches of medicine, by three physicians selected by the board, as I was told, each to represent one of the three great medical colleges of this city.

In the event, I was so fortunate as to stand first, with a rating of one hundred per cent. in each of the branches. My friend Dr. Condict W. Cutler, then recently of Bellevue Hospital, stood second, with ninety-eight per cent.; and Dr. Charles S. Mack, then recently of Chambers Street Hospital, was third, with ninety-three per cent.

According to the law, the Police Commissioners should appoint one of the first three. In my innocence and freshness I actually supposed that the heads of the municipal police force would do as they should do—that they would obey the law as a matter of course.

As I look back upon the affair, this belief—this child-like trust on my part in official honesty of intention, strikes me as most ludicrous and amusing. But at that time I really supposed that the result of Civil Service rules was to give the appointment to the candidate reaching the highest rating.

Time passed, and no appointment was made. At last, becoming worried, I took several letters of introduction from eminent business men and called upon the Police Commissioner—since retired from office—whose turn it was to appoint (the four commissioners appoint in rotation).

I saw him alone in his room at Police Headquarters. He read my letters, also the paper announcing my stand-

ing. Then he said: "Civil Service Reform be damned! I will not, as we say, *hang you up*, but will tell you plainly that neither yourself nor any doctor who passed that examination will be appointed. I have promised that place to a doctor who did not take that examination, and after your period of eligibility has expired there will be another examination, and my man will go in."

If the commissioner had knocked me down he could not have surprised me more than he did by that speech. In reflecting upon it, I can only account for his surprising frankness by the remembrance that we were alone, and any subsequent repetition on my part would probably be met by a simple denial on his part, and there the matter must rest. Though I felt bitter enough at the time, I am now rather grateful to this individual in one respect, for he might have *hung me up* (kept me in suspense by postponements and false promises) indefinitely, instead of giving me a prompt despatch, as he did.

I called next upon all the individual members of the Civil Service Board, gave a brief statement of the facts just narrated, offered to make affidavit thereunto, and asked them to endeavor to prevent such a wilful and contemptuous infraction of the spirit of the law, by prolonging the period of eligibility of successful candidates for medical positions until at least some one member of a given eligible list had received an appointment. This certainly was a reasonable request, and would, if carried into effect, have blocked the Police Commissioner's scheme to violate the law.

These gentlemen listened to me politely, seemed not to care about the matter particularly, and nearly a month later sent me a note, through the secretary of the board, stating that they would not take any action at present.

That ended the matter so far as my efforts were concerned. I did not appeal for justice to the public, because the use of the daily papers for such a purpose is not open to self-respecting physicians.

At length the time arrived—one year—when we who had passed that examination were no longer eligible. And, of a truth, none of that list were ever appointed. Shortly thereafter I heard that there had been another examination. Differing from the first, this examination was not, as it should have been, advertised in the medical journals. I am told that it was only advertised in the *City Record*, the official and legal organ of New York City appointments. Certain it is that not more than half as many doctors appeared at this examination as at the previous one, they being mainly those who had political friends to notify them. Very few of the first list were present, or had even heard of the second examination until it had actually been held.

Owing to the death of yet another Police Surgeon, during my year of eligibility, and to the fact that the commissioners now retired a couple of surgeons who were over sixty-two years of age, there were four vacancies. These were filled from this second eligible list, by selecting four men, one of whom was the physician who, as I have stated, had been promised the appointment more than a year before. This gentleman is the nephew of an eminent statesman, to whom the commissioner aforesaid was under obligations. (I would not have it supposed that he was unworthy. I have reason to believe him an excellent physician.) Another appointee was a close relation by marriage to the leader of one of the city political factions; and this leader secured his appointment. The remaining places went to two men who had served in the army during the war. They were both near the foot of the list, having shown a poor standing. But the commissioners in this case had no choice, the law being mandatory regarding veterans of the late war.

The two candidates who had stood highest upon this eligible list, respectively, Drs. Charles E. Quimby and Condict W. Cutler, not having enough "pull," were ignored, passed over, and never received an appointment.

Some little good to others came out of my own discomfiture, in this wise: I wrote the Hon. John Jay, Chairman of the State Civil Service Board, saying that it seemed to me only courteous that all the successful candidates of a given examination should be specially notified, when their eligibility has expired without appointment, of the time and place of the next examination.

Mr. Jay in his reply stated that he agreed with me, and would endeavor to have this point carried into effect throughout the State. This, I am told, has since been done.

Between the time of which I have been writing—1885 and thereabout—and the present date, I have heard from various sources, authentic, I believe, occasional reports of medical appointments to our city departments of which we cannot be proud. During these years I have had quite a number of applicants for quizzing in preparation for the city Civil Service medical examinations; and I have always advised the gentlemen in question, as in conscience bound, not to waste their time. If they have a "pull," seventy per cent.—the under limit—will suffice. If they have not a "pull," a higher per cent. will not avail anything.

It may perhaps interest your readers to know of the latest proof of the kind whereof I speak. I give it with the brief preface, that it is only a fair assumption that it is not the only case of its sort. There are probably others of which I do not happen to know.

Dr. A B C, a former student of mine, did not, until after the fact, hear of the examination held this summer for the "Summer Corps" of physicians to assist the regular corps of the Board of Health. He was but a day or two late, and determined to try political influence. In this he was successful, for a well-known city official, of his own language and religious belief, procured for him a copy of the questions, which he answered at his leisure, at home, and doubtless to his own satisfaction. His paper was then duly handed to his political friend, was slipped in among the other papers, and in a short time he received his appointment as a member of the "Summer Corps," in which he remained throughout the season.

I have reason to believe what the doctor said to me. In the first place, he had no reason for deceiving me. But, aside from this, I know that he was elsewhere when the regular examination was held, and I know also that he was, nevertheless, in the Summer Corps.

If it should be said that I owe it to the profession to report, publicly, the names of such flagrant violators of the law, I can only reply that I would gladly do so; but that this and such other instances as have come to my notice were told in confidence, which, although unsought on my part, I cannot break.

I presume that the Civil Service Board will find it easier and simpler to disbelieve my statements than to keep that sharp watch over the *personnel* of their department and the purity of their "reform" which they devote to their private finances.

The medical profession in this country seldom bestirs itself in public matters even where its own weal is concerned. More is the pity. We can hardly expect others to show a greater interest in our own affairs than we ourselves discover.

If such a large body of educated men as the physicians of New York were really to take some concerted action, and maintain it loyally, what could they not accomplish in the way of abating political abuses? If a standing committee, wisely selected, from the Academy of Medicine, or the County Society, or both, should make earnest and continued endeavor, perhaps the public at large might come to understand—as an example—that their lives might be better protected against plague and pestilence than at present; that the health-officer to a great port should be one in fact, and not alone in name: one who has demonstrated some ability in preventive medicine, not one who is selected solely for political and partisan reasons—his office being merely a source of revenue to his party.

It may be, too, that such a fighting committee might

succeed in wiping from our name the stain and reproach which is conveyed in the exclusion of a physician and the appointment always of some politician as the head of our Board of Health. Even such serious matters as life and death have their ludicrous side at times; and what could be more grotesque and worthy of comic opera than debarring a medical man from the head of a department which absolutely demands for the protection of our citizens a thorough medical training?

It would be well for our standing committee to keep an eye upon the Civil Service Commissioners with regard to the various medical examinations, and the resulting appointments. Such scrutiny would not be pleasant for these gentlemen, but, in view of the facts, who shall say that it would be time ill spent?

I am told that the board have not always been wise in their selection of physicians as medical examiners. That is a matter wherein, necessarily, their judgment cannot be of the best. It would be a modest and becoming admission of fallibility on their part if they would request the Academy—for instance—to name responsible and able men, annually, for this purpose; and these examiners should endeavor to give their examinations as practical a cast as possible.

And finally, one—possibly two—further reforms are needed in our vaunted Reform. First, the man who heads the successful list should be the man appointed; and the wording of the law should make this inevitable. Otherwise, as now, the thing is a farce and a sham reform.

Regarding the second, I speak with much hesitation. It has reference to the preferment of veterans over men who may have been shown by the examination-test to be the more able physicians.

I would not have it thought for a moment that I do not feel hearty respect and admiration for these brave men, as every true American must do. And I sympathize with the public sentiment which shows them honor in every proper way. But is this a proper way? I would not be dogmatic. Perhaps my views herein are wrong ones. But reflection would seem to show that this clause is an excrescence in Civil Service laws. So far from being a proper part of it, this provision seems to me to antagonize directly the theory on which the whole fabric of examinations rests; which is, as I understand it, that the man of greatest demonstrated fitness is the proper man. Sympathy, gratitude, admiration of personal bravery, or other emotion, is quite foreign to the matter. If it be objected that the veteran should nevertheless be appointed because examination is often a fallacious test of real ability—which is, up to the present time, certainly the truth—that is largely the fault of the examiner and the kind of examination. It could be made a very fair test, if sufficiently practical and not too brief and hurried.

It is probably expecting too much to hope for a change for some years to come in the law regarding veterans. And it is very probable that some of your readers would support it, and disapprove any change in this regard. As I have said, this may well be considered ground for amicable difference of opinion. But in all other respects I feel sure of the earnest concurrence of a united profession in what I have indicated as a line of true reform.

Very respectfully,

ROBERT H. M. DAWBARN, M.D.

345 WEST FIFTY-SIXTH STREET, NEW YORK.

## STATE EXAMINING BOARDS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: If not intentional, it was certainly a happy coincidence, that in THE RECORD for November 9th, together with a letter advocating "A Medical Examining Board for New York State," there appeared, as it were in refutation of it, an extract entitled "The Trade of Medicine in Germany." From the latter one may form a slight idea of some of the beautiful results which ensue whenever the state begins to "regulate;" for it is an often observed fact, that when legislative aid has once been involved, no one can predict where its mischievous spirit of interference will stop.

The history of the progress of medicine in the United States is—in spite of every shortcoming—that of a steady and healthy upward movement, with either no legislative "regulation" whatever to hamper it, or hardly any worth mentioning. Year after year has witnessed a constantly increasing demand, as well for a higher standard of general education as for a wider range of special learning, from him who essays to enter the ranks of medicine. And to keep pace with these demands, a progress as uninterrupted has in general marked the policy of the medical schools; witnessed everywhere by the addition of new departments, and the eager adoption of every improvement in the means of teaching. It is a matter of common remark and congratulation how this spirit of advance, which has been gradually evolving, has, in recent years, gone forward with giant strides. Let him who graduated but ten years ago contrast his opportunities for learning with those now presented in the city of New York. Let him think of the stately college buildings and the number of magnificently equipped laboratories that have sprung into existence in that short time; let him remember the two excellent schools devoted solely to the instruction of post-graduates that have been founded; and then let him ask himself to what these beneficent changes are due. Will anyone be rash enough to assert that one jot or tittle of all this improvement is due in any way to legislative aid? The benefits we now enjoy are wholly the outcome of the enlightened demands of public opinion; and it is to public opinion alone, where democratic institutions prevail, that every citizen must look for progress and reform. This it is, and not the paralyzing aid of legislation, that we have to thank for every good we now possess; and may that shameful day be far distant when the medical profession of the Empire State, hat in hand, shall knock at the door of the Capitol at Albany—whose very ceilings cry "fraud!"—and beg "protective regulation."

Look again, and on the other side see the workings of those medical departments in which politics now has a hand. Observe what enlightened pathologists our coroners are, what acute sanitarians usually grace the heads of our boards of health, what eminent epidemiologists preside at the entrance of our harbor.

But suppose we are to have a State Examining Board, who is to compose this board? Regulars, homœopaths, and eclectics, of course, since all being on an equal footing before the law, all are entitled to representation, and all will claim it. And does any man for a moment suppose that a license issued by such a heterogeneous medley will command more respect than that which is now granted through a college diploma? Since it may justly be claimed that the health of the soul is, if anything, more important to the State than the health of the body, it would be just as logical to advocate a State Examining Board in theology, to be composed of Christians, Jews, Mormons, and Buddhists.

All legislatures have granted in the past, and still continue to grant, charters to institutions which prove themselves of shady reputation. This fact alone is in itself a guarantee that in the formation of a State Board of Examiners every kind of "influoence" but the proper one might be brought to bear.

But instead of pleading the baby act, and crying for legislative "protection," be it ours to choose the nobler part—be it ours to continue that manlier policy of relying upon ourselves for the command of public respect. Let us persist upon this path, which, as heretofore, has been trodden with honor and success, knowing that every true advance can come only from within—never from without.

And as my friend Dr. Wyeth has invoked the Academy of Medicine, let me do so too.

Moved by the same spirit of appreciation of the elevat-

ing impetus that freedom gives, which led the Academy a few years ago to abandon a worn-out "code" to those who still might feel the necessity for one, may it now and always set its face against any reactionary movement which, under the plausible guise of "regulation," opens the door to the shackling of that free spirit which for its perfect development asks no favors, craves no boon, scorns every special privilege, demands naught save *liberty*.

WALTER MENDELSON, M.D.

November 14, 1889.

## HOW IS THIS?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The last issue of THE MEDICAL RECORD contains a report of the Seventh Annual Meeting of the American Rhinological Association. In this report is mentioned a paper on "Ocular Reflex Symptoms in Nasal Diseases," presented by a Dr. C. H. Moore, of Indianapolis. The substance of the paper and the criticisms derived therefrom are literally copied from an article entitled "Reflex Ocular Symptoms in Nasal Affections," written by me in 1885, read before the New York Academy of Medicine, and published in THE MEDICAL RECORD of January 30, 1886. My conclusions and those of Dr. C. H. Moore placed in parallel columns will demonstrate the plagiarism:

| GRUENING, 1886. | MOORE, 1889. |
|---|---|
| The cases here presented have the following features in common: | The cases reported had the following symptoms in common: |
| 1. Burning and smarting sensation of the lids or of the eyes, more pronounced in the morning than in daytime. | 1. Burning and smarting sensation of the eyelids, especially in the morning. |
| 2. Inability to fix an object in ordinary daylight | 2. Difficulty in distinguishing an object in ordinary daylight. |
| 3. Increased vascularity of the conjunctiva, and lachrymation upon slight provocation, such as a mild current of air. | 3. Increased vascularity of the conjunctiva, and lachrymation on exposure to the air. |
| 4. Sound condition of the eyes and their appendages. | 4. The sound condition of the eyes and their appendages. |
| 5. Inefficiency of the ocular and the general treatment. | 5. Failure of the ocular and the general treatment. |
| 6. Efficiency of the nasal treatment in spite of the absence of nasal symptoms. | 6. The efficiency of nasal treatment. |

By giving publicity to this card you will follow the tenet of *suum cuique*, under which THE MEDICAL RECORD has grown and thriven.

Truly yours,

E. GRUENING, M.D.

NEW YORK.

## THE OPPORTUNITIES OF RELIEF FOR THE POOR OF NEW YORK SUFFERING FROM DISEASES OF THE RECTUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am the recipient of a circular issued by a well-known "medical corporation"—here in New York—that advertises "a clinic for diseases of the rectum, to be under the personal care of Dr. ——." It begs reference to this clinic of persons suffering from this class of diseases, and adds:

"There has been, as you know, very little special care of these very deserving cases, and we trust that the profession will aid the Hospital and Dispensary in giving them special and proper care."

This statement—as you are aware, sir—is absolutely false, and its falsity is only equalled by its absurdity. You and I know perfectly well, from personal knowledge and attendance at the regularly organized general dispensaries and hospitals of New York, that these "very deserving cases" *do receive* "*special and proper care*"—more, that there has never been any period in the history of the city of New York, from the time the illustrious Bush practised general surgery in this community—over fifty years ago—up to the present moment, when such assistance—of the best grade too—has not been afforded "when called for."

I ask the insertion of this communication to attract the attention of those who do not know of the good service rendered in the general and well-organized dispensaries and hospitals of New York, and of those whose credulity is imposed upon to maintain too many "institutions," at a great cost, for many other than purely charitable purposes.

The circular is signed by five members of "the hospital committee of this institution," the majority of whom have at least had opportunities of knowing that the appeal is an improper one, and that my statements are strictly correct.

MORRIS H. HENRY, M.D.

581 FIFTH AVENUE, NEW YORK,
November 18, 1889.

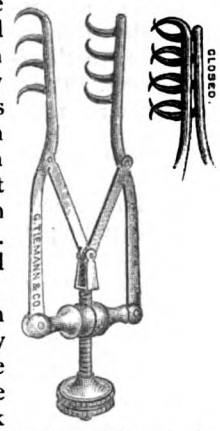
# New Instruments.

## A NEW MASTOID RETRACTING SPECULUM, RETRACTORS, AND LANCE-POINTED DISCISSION KNIFE.

BY FRANK ALLPORT, M.D.,

PROFESSOR OF CLINICAL OPHTHALMOLOGY AND OTOLOGY IN THE UNIVERSITY OF MINNESOTA.

I DESIRE to ask the notice of the profession to an instrument I have devised for the purpose of facilitating the operation of opening the mastoid cells. In this operation it is desirable that the two flaps made by the incision be kept widely open, in order that the work upon the bone may be kept well under observation. I have been in the habit of obtaining this result by two tenaculums placed in both sides of the opening, and held apart by an assistant. The instrument here shown accomplishes the same result, and it does away with the necessity of an assistant for this purpose. I have called it a "mastoid retracting speculum."



The arms of the speculum can be closed or opened by the screw-button, at the base of the instrument. The hooks are made to interlock nicely, so that they may be introduced into quite a small aperture. The hooks have sharp, but not cutting, points, and the whole instrument is made short and strong, in order that considerable force may be used in opening the blades—which may become necessary in case of great thickening or swelling of the tissues over the mastoid process. The instrument may be introduced into the incision with its base either up or down. When thus introduced and widely expanded, and the parts wiped as dry as possible, a fine view of the underlying bone may be obtained, and the ease of the operation much facilitated. The wide expansion of the blades also aids in the stopping of the hemorrhage from the soft tissues, which also adds to the ease of the operation by presenting a much clearer view to the eyes of the operator. This instrument, as well as others referred to in this article, has been manufactured for me by Tiemann & Co., of New York, where they may be obtained. For the same operation, I have also modified an already existing instrument, by causing to be made a pair of grippling hooks upon a small scale.

These hooks have solid steel handles, and may therefore be rendered perfectly aseptic. They are to be introduced into the incision, and pulled apart by an assistant. A pair of these instruments is efficient, but not more so than the speculum, and necessitates an extra assistant, and consequently another pair of hands around the field of operation. I have called these hooks "mastoid retractors."

I wish, also, to present a modification of other discission needles. The blade is very thin and has a double cutting edge, which extends almost down to the stop-point. Just before reaching this point the edge is dulled, so that, in working the needle around inside of the eye, it will not cut the corneal tissue. The slanting shape of the blade renders its introduction into the cornea extremely easy, and the double cutting edge facilitates the breaking up of the lens-substance.

This instrument I have called a "lance-pointed discission knife." The belly of the blade, as shown in the engraving, is wider than will be seen in the instrument.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 24 to November 30, 1889.*

HAVARD, VALERY, Captain and Assistant Surgeon. By direction of the Secretary of War the extension of leave of absence, granted in S. O. 240, October 15, 1889, from this office, is further extended one month. Par. 1, S. O. 272, A. G. O., November 21, 1889.

BALL, R. R., First Lieutenant and Assistant Surgeon, Fort Riley, Kan., will proceed to Fort Sill, Ind. Ter., and report to the commanding officer for temporary duty at that post. Par. 2, S. O. 173, Department of Missouri, November 21, 1889.

PILCHER, JAMES E., Captain and Assistant Surgeon. By direction of the Secretary of War is relieved from duty at Fort Wood, N. Y. H., and will report in person to the commanding officer at Fort Clark, Tex., for duty at that station, reporting also by letter to the commanding general, Department of Texas. Par. 3, S. O. 276, A. G. O., November 26, 1889.

COCHRAN, JOHN J., Captain and Assistant Surgeon. Leave of absence for fifteen days is granted, to commence about December 1. 1889. Par. 8, S. O. 272, Division of the Atlantic, November 27, 1889.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 30, 1889.*

GUNNELL, F. M., Medical Director. Placed on the Retired List, November 27, 1889.

GAINES, J. H., Surgeon. Ordered to duty at Army and Navy Hospital, Hot Springs, Ark.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 30, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 28 | 8 |
| Scarlet fever | 49 | 8 |
| Cerebro-spinal meningitis | 1 | 2 |
| Measles | 38 | 3 |
| Diphtheria | 70 | 17 |
| Small-pox | 0 | 0 |
| Variola | 6 | 0 |
| Cholera | 0 | 0 |

TRIPLETS WITH BUT ONE PLACENTA.—Dr. C. Butler, of Shepherdstown, W. Va., writes: "Having noticed in THE RECORD during the last few months several cases reported of twins with one placenta, I thought perhaps the following would be of interest to your readers. I was called on July 12, 1889, to attend Mrs. A—— in labor, that being her ninth confinement. Labor advanced rapidly, and in less than one hour she was delivered of triplets, two girls and one boy. The births followed each other so quickly that I scarcely had time to ligate and sever the cords. There were now three cords protruding, and in a few minutes the pain set in again and a placenta, to which all three of the cords were attached, was expelled." Dr. A. E. Aultz, of Richmond, Ky., also reports a case of triplets with three cords and but one placenta, as follows: "I would like to report a case of triplets with one placenta and three cords, two of which were attached near the periphery within one inch of each other, the other being inserted at a point about six inches from them. The placenta was very firmly adherent. Upon being called to see the patient, Mrs. Caroline B——, in labor, I made an examination and gave the opinion that she would bear twins. At four o'clock, two hours after I had been called, the first child was born by first position; in three minutes the second child was born by a feet-presentation, and in twelve minutes a third child was born, also by the feet. Two of the children weighed seven pounds each, and the third six pounds. The placenta (and only one placenta) was adherent, and was removed with difficulty. The children and mother are doing well. Mrs. B—— is forty years of age and the mother of sixteen children."

LOCAL TREATMENT OF WARTS.—Dr. Altschul (*Centralblatt für Chirurgie*, No. 18, 1889) recommends mercurial ointment, to which arsenic in the proportion of five or ten per cent. has been added, as an application for the cure of warts. This is spread upon muslin and bound over the warts. When the latter become painful and excoriated, the excoriations are cauterized with fuming nitric acid. Then tar-ointment is applied. This treatment is certainly energetic enough and ought to destroy warts if anything will.

BICARBONATE OF SODIUM IN MILK.—Hitherto it has been deemed permissible to add soda bicarbonate to milk to assist in its preservation, but now the Council of Hygiene of the Seine has condemned the practice as one of danger. The transformation of milk-sugar into lactic acid, in milk so adulterated, gives rise to a lactate of soda which is purgative, and frequently a source of almost uncontrollable diarrhœa in infants. Consequently, the Council in its *Bulletin* decides that: "Soda shall no longer be permitted in milk, which is an aliment of the first order, and very often prescribed for invalids and children."—*Medical Age.*

GREEN SOAP IN CARIES.—Dr. Kollmann has obtained excellent results, in cases of caries, from the use of green soap, which he rubs in with a sponge, or the palm of the hand, over the neck, back, and the posterior surface of the thighs. These applications are made two or three times a week, and best at night, the quantity of soap used varying from 25 to 40 grammes. The soap is left on for half an hour, and is then washed off with warm water, and the patient sent to bed. Except in cases of chronic periostitis, or caries of the pelvis, spine, or lower extremities, the patient is allowed to follow his occupation during the day. Change of diet and cod-liver oil are not essential during the time of treatment, although they may hasten recovery. The results of this treatment were astonishingly good, the average duration being four and one-half months. The author thinks that in caries there is an excessive quantity of lactic acid in the blood and tissues, which is neutralized by the alkaline property of the soap. —*The Cincinnati Medical Journal.*

DR. NICHOLAS I. KOZLOFF, a well-known physician and one holding a most important position in the Russian public service, died recently in St. Petersburg of a cardiac affection.

## Original Lectures.

### ON VITAL AND MEDICAL STATISTICS.[1]

BY JOHN S. BILLINGS, M.D.,
UNITED STATES ARMY.

LECTURES III. AND IV.

THOSE of you who are familiar with the history of medicine in the early part of this century will remember the great anticipations which were formed and expressed by prominent physicians as to the results which might be expected from what was called the system of statistical medicine, introduced in the Paris School by Louis and his contemporaries. This was not exactly a new system, but rather an attempt to methodize an old one, *i.e.*, to present the experience of different physicians in such a way that comparisons might be accurately made, and the results mathematically expressed.

In this so-called numerical method, all the details of each case observed are to be noted as far as possible, without any special regard to whether these details may appear to the observer to have any special connection with the course of the case or its termination, or not. When a number of such cases have been collected, they are to be compared in all their details, showing, in round numbers, how many present such and such particular circumstances, and how many do not.

In order to make a useful application of this method it is, of course, necessary that the different observers shall be describing substantially the same thing; that is to say, the disease to be observed must present a definite series of symptoms so that a person properly qualified will recognize its existence without any liability to error. It should also be a disease which follows a tolerably regular and definite course, having a commencement which can be recognized. Such forms of disease include the so-called specific diseases, and acute affections of particular organs. The method is most applicable to surgical cases of all kinds, including those which come under the domain of the various specialties.

As regards details of pathological anatomy, it has been pointed out by Dr. Flint that the statistical method can apply only to those changes which can be appreciated by the senses after death, and that there being but one constant lesion found in typhoid fever, viz., the softening of Peyer's patches in the small intestine, the statistical method gives us little assistance in the investigation of the pathological condition of this disease.

We may note, however, that, if it be admitted that typhoid fever is due to a specific bacillus, as seems now to have been fairly demonstrated, and that this bacillus has been discovered and verified mainly by the application of experimental methods, it is, nevertheless, true that the results thus obtained have met with a general and prompt acceptance, mainly because the application of statistical methods to the circumstances of outbreaks of this disease in different communities are in perfect accord with the bacillus theory of its causation.

This merely illustrates the general law that the experimental and the statistical[2] methods must be used together, and that their results must be in accord, to produce full confidence in the results obtained by either alone.

The sanguine advocates of the numerical system of Louis supposed that all that was necessary to discover all the laws with regard to the propagation of any disease, and the true value of any or of all methods of treatment proposed for that disease, was simply the collection by different observers of all the data which could be obtained from individual cases, and the tabulation of these according to a certain fixed and almost mechanical system of permutations and combinations, by means of which the various symptoms are brought together in groups, in connection with the results observed, and that thus should be obtained a true scientific basis, or, as they commonly phrased it, "the science of medicine."

We can now see plainly enough that this is, from the nature of the case, impossible; that the data obtained by different men can hardly ever be made fully comparable, and that, however complete they may be, the number of factors which combine to produce such a result as the production of a particular form of disease in a healthy organism is so great that, from mere statistics of observation, we can never obtain scientific knowledge as to the relative part which each factor has taken in producing the result. This can only be done by experimental methods, in which the influence of one particular factor can be applied and those of others eliminated as far as possible; and the great advances which have been made toward obtaining a scientific basis for practical medicine within the last twenty five years are, in the main, due to the experimental method. So soon, however, as we have, by the investigation of particular cases and by experiments, obtained a more or less probable theory as to the cause and mode of diffusion of a particular form of disease, the outbreaks of that disease in a community afford an invaluable means, in many cases, of testing the truth or falsity of the theory.

It must be admitted that the probabilities of error are much greater in medical than in vital statistics, and this for a number of reasons. The first is that no two observers examine, or interpret, a disease in precisely the same way, and hence it is extremely difficult to collect a mass of observations sufficiently large to form a basis for statistical reasoning. Those who wish to be scientifically accurate in the use of such material are usually compelled to deal with a very limited number of observations, because they cannot obtain a large number upon which they can fully rely.

The best data are, for the most part, those which lie in the field of surgical observation, since here the symptoms observed, the methods of relief applied, and the results obtained, are tolerably definite, and there is not likely to be much difference in the methods of recording them.

The methods of medical statistics differ fundamentally from those used by the vital statistician in that they usually have no relation to the phenomena observed in the normal, healthy, living population. The physician inquires, out of a thousand cases of children or of old persons that have been treated, how many times has this particular disease been met with; or, in a given number

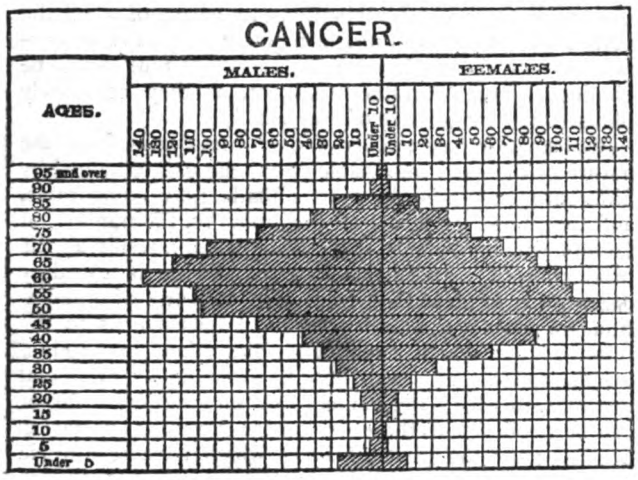
[1] The Cartwright Lectures, delivered before the Alumni Association of the College of Physicians of New York, November, 1889.

[2] An interesting discussion on the value of the statistical, or numerical method, as applied to medicine, will be found in the Bulletin of the Royal Academy of Medicine for 1836, vol. i., p. 622 *et seq.* The immediate cause of the discussion was a paper by d'Amador attacking the value of the methods of Louis and criticising the results obtained. Bouillaud, Chomel, Double, and others took part in this discussion, *pro* and *con*; and while no definite conclusion was reached, it was very evident that the dispute was rather a matter of definition than of anything else.

of cases of this disease, what proportion have died? This method is, in fact, practically the only one which is available to the physician; but the vital statistician, if dealing with disease, will want to know what are the probabilities that a male between twenty and thirty years of age will contract a given disease, such as phthisis or typhoid fever, and for this purpose he wishes to know the whole number of cases observed in a given population, and the number of the population furnishing those cases, in order to establish the ratio.

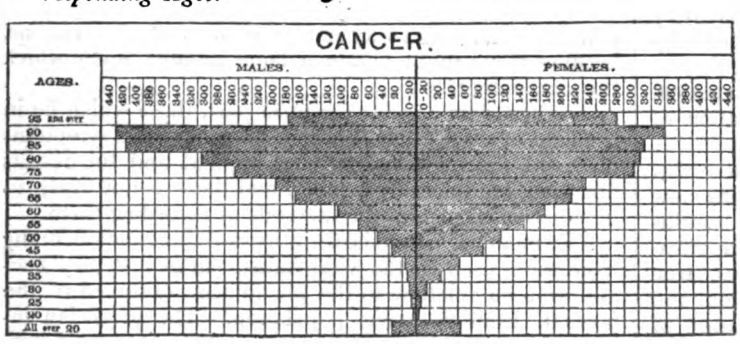
Bertillon illustrates this in his comment that the small number of deaths of old men attributed to typhoid fever might lead the physician, from his point of view, to say that typhoid fever in old age is a rare disease; but the vital statistician might conclude that the rarity of the disease in old age was simply due to the small number of those living at that period.

*Deaths from Cancer at Certain Groups of Ages in* 1,000 *Deaths Caused by this Disease.*



This may also be illustrated from the statistics of the 13,000 deaths reported as due to cancer in the United States during the census year 1879–80. The first of the two diagrams before you shows the proportion of deaths from cancer at different ages in the manner in which it would be calculated from the records of physicians or hospitals; namely, the ratio at each age to 1,000 deaths caused by this disease. From this diagram it would appear that cancer is most fatal about the age of sixty. If, however, we compare the deaths from cancer at each age with the total living population at that age, after the methods of the vital statistician, we obtain the figure shown in the second diagram, which indicates that the mortality from cancer increases with advancing years to the age of ninety, and that the reason why the number of deaths from this cause diminish after sixty is simply because of the less number of living population after that age.

*Deaths from Cancer of Persons Over Twenty Years of Age, with Distinction of Age and Sex, in* 100,000 *of Population of Corresponding Ages.*



In discussing the tabulation of the returns of cases of acute rheumatism, in the "Collective Investigation Record," Dr. Whipham gives the number of cases in each occupation out of 655 cases recorded. Of these, 71 were domestic servants; 16, agricultural laborers; 13, farmers; 10, grocers, etc. He comments that the number of domestic servants, 71, is a remarkable occurrence, and proceeds to account for it by the consumption of alcoholic drinks, etc.

It is evident, however, that absolutely no conclusions can be drawn from these figures, since there is no definite proportion between the number of domestic servants attended by the physicians who made the reports and the number of domestic servants in existence, nor is there any relation between any of these figures and the number of domestic servants attacked by rheumatism. The only way in which this factor could be brought in in such statistics would be with reference to frequency and character of complication, or as to relative fatality of the attacks in comparison with other occupations.

The fact that in each case of sickness there are many different circumstances which combine to produce the result is not, as Louis remarks, a valid objection to the use of statistical methods for the purpose of estimating the influence and relative importance of each of these influences; it is rather an argument in favor of their employment. Counting is better than guessing, and when it gives contradictory results as applied to two groups of cases, it indicates that some circumstances have not been taken into sufficient account, and that further inquiry is necessary. In the body of the sick man, as in the test-tube, like causes under like circumstances will produce like effects.

Admitting that the chances of error in medical statistics are very much greater than in those relating to vital statistics, it does not follow that they have no value. It simply increases the desirability of collecting a large number of facts before proceeding to draw any definite deductions.

In statistics with regard to therapeutics, we have to take account of the various influences which the condition of the organism exerts upon the results before we can fairly estimate the action of the new and special influence which has been introduced in the shape of an action of a drug, or a particular mode of treatment. In any event, such statistics, even when derived from a small number of cases, serve to indicate lines of investigation, and to ask questions, if they do not answer them. As Legoyt remarks, two pneumonias do not resemble two dice, each having the same number of faces and of numbers, but rather dice with an unequal number of faces and different numbers.

The greater part of our pathology and therapeutics has not been derived from statistical observation. It is not by this means that the diagnosis of small-pox, or of scarlet fever, or of rheumatism, has been worked out, or the fact that the ulceration of the intestinal glands belongs to typhoid fever, or the presence of gummy tumors to syphilis; nor has it been by this means that the transmissibility of certain forms of disease by contagion has been proved. Whenever a necessary and logical connection between a particular cause and the resulting phenomena has been established, statistics are of little or no value in demonstrating the connection. In every case the result must follow the cause, as it does in a chemical experiment, and a few repetitions of such experiments give as great a degree of certainty as a thousand or more.

The chances of the occurrences of a certain event in relation to cause can only be mathematically calculated when the totality of the possible causes of the result remains the same under the different circumstances investigated. This is one of the chief reasons for the impossibility of drawing positive conclusions from medical statistics properly so called.

The consequent condition is one that I have already mentioned, viz., the application of the law of large numbers and the consideration of the limits of positive error.

The services rendered by statistics to medical science are by no means so great as was hoped by those who first proposed the application of this method; partly from the nature of the case, partly from the wrong application of statistical methods to groups of cases to which they are in nowise applicable. What result, in fact, can we expect from statistics applied, for example, to a number of cases of fever before the distinction between typhus, enteric, and relapsing fevers was understood?

The results of medical statistics will not apply to the treatment of any particular case. They can never prove that bloodletting should be employed in all cases of pneumonia, or that it should never be employed in any case of pneumonia. Even the results obtained from the most satisfactory medical statistics will only be found use ful to the physician in directing his treatment, in the absence of any special indications in the particular case which he has before him.

The data upon which to base medical statistics must be obtained either from published records, from unpublished memoranda collected by means of correspondence, or by the so-called collective investigation methods, or from personal experience. The published data include such records of private practice as are given in journals, transactions, monographs, etc., records and statistics of hospitals, statistics of public medical services and of medical and life-insurance societies.

In many respects the crude data in the form of records of individual cases are the most reliable; but the labor of collecting and combining them is great, and we desire, therefore, to use the statistical tables prepared by previous workers, as far as they are available, for the particular inquiries which we have on hand.

Detailed reports of cases, such as are suitable for use in statistical work, are not over-plentiful. In the majority of cases the individual data are not given. We have only summary statements of tables of results. This is the case with regard to much the larger part of the great mass of reports of results of hospital and asylum practice which have been published during the last hundred years, either in the form of separate annual reports or in summaries for journals or societies. These reports give some information as to the prevalence of certain diseases in certain places at certain periods of time, and in this way have some historical value, but they do not show the proportion of cases of disease or death to the living population in which these occur, and very few of them give the data by sex and age in the manner required by the statistician. Some of these calculate death-rates with reference to the total number admitted during the year, others to the total number treated, which includes those remaining on hand at the beginning and those admitted during the year, and others to the total number disposed of during the year by discharge, transfer, or death. A few of them give the average daily number under treatment during the year and the average number of days' treatment for each case, sometimes making a distinction of sex, but almost never of race or age.

Comparisons of gross death-rates of different hospitals, however calculated, are of little value for the purpose of determining either the sanitary condition of the place, the skill of the medical staff, or the merits of the particular system of treatment, owing to the great variations in the class of patients admitted. Of course, the statistics of hospitals for special classes of diseases can only be compared with those of the same kind, and, even for general hospitals, the fact that the gross death-rate of one is higher than that of another proves very little.

In a paper by Dr. Guy on the rate of mortality prevailing in the general hospitals of London, he compares the death-rates of King's College Hospital, with which he was connected, for the first five years of its existence, 1840 to 1844, with the five years from 1857 to 1861. During the first period it was an old building, in a bad locality, and greatly crowded, and without any reputation as a hospital or as a medical school. During the last five years it was in a new building, with excellent sanitary arrangements and with an excellent reputation. He calculated the death-rates on the number of admissions to the hospital. The rate for the first five years was 8.4; during the last five years it was 10.85. He concludes that a higher rate of mortality may be due to causes very different to sanitary defects in the building and want of skill in the medical staff, and that in a large city, in the case of a hospital enjoying similar sanitary advantages, the rate of mortality is mainly determined by the reputation of its hospital staff among the public at large and among its own pupils, which reputation influences the proportion of grave and dangerous cases which are sent to it.

In comparing hospital death-rates it is now generally agreed that it is best to make use of the death-rates in relation to the total number of persons disposed of by discharge, transfer, and death for a series of years. Comparison of the number of deaths with the admissions only, is apt to give very misleading results. A better method than this is that of Bertillon, who adds to the number at the beginning of the year one-half the sum of those admitted and of those going out. It is also desirable to know the ratio of deaths and discharges to the mean population of the hospital, which is obtained by dividing the number of days of treatment by 365; but in this connection it is to be remembered that when the mortality is calculated with relation to the number of days' sojourn in the hospital, those physicians who keep their patients the longest will show the lowest death-rates.

In this connection may be mentioned a curious error contained in the hospital statistics of France for the years 1833 to 1852, inclusive. Here an attempt was made to calculate the percentage of death on the total number treated, but the way in which this was done was to add the sum-total of those remaining at the end of each of the twenty years to the number of those admitted during the respective years, giving an average death-rate of 8.3, the figures being: Number admitted during the twenty years, 8,818,501; sum of those remaining at the end of each of the twenty years, 2,204,676; making a total of 11,023,177.

Here it will be observed that a large number of patients are counted twice over, for, instead of the total remaining over at the end of each of the twenty years, there should have been taken only the total remaining at the beginning of the record, which was 99,262; so that the number of patients has been improperly increased by 2,105,414, with a corresponding improper lowering of the deathrate, which should be 10.3 per cent. instead of 8.3.

One of the earliest statements in relation to the mortality of hospitals is that in Sir William Petty's work on "Political Arithmetic," to the effect that in the year 1685 the proportion of the deaths to the cures in St. Bartholomew's and St. Thomas' Hospitals was about 1 to 7.

In the old Hôtel Dieu, in Paris, for the years 1770–80 the ratio of the number of deaths to number treated was twenty-five per cent.

In the hospitals in Paris in 1822, for over 40,000 cases the mortality was 12.5.

In the Charité Hospital in Berlin, from 1796 to 1817, twenty years, the death-rate was 16.66. In the Imperial Hospital at St. Petersburg, from 1803 to 1817, fourteen years, the deaths were 22.22 per cent. of the number treated.

I have prepared an extensive series of tables of death-rates in hospitals, from which these are merely selections; but my conclusion from a careful examination of them is that they are worthless for any scientific purpose, and that such statistics are useless unless they give the death-rates by groups of ages.

The following table gives the means of comparing some ancient and modern death-rates.

| Hospital. | Period. | Death-rate of treated. | Death-rate of disposed of. | Average stay in hospital. |
|---|---|---|---|---|
| Guy's Hospital, London | 1730–40 | 13.80 | | |
| St. Thomas' Hospital, London | 1730–40 | 11.10 | | |
| St. Thomas' Hospital, London | 1870–76 | 12.15 | | |
| French hospitals | 1833–52 | 10.30 | 10.50 | |
| Charité Hospital, Berlin | 1878–87 | 9.60 | 10.40 | 29.3 |
| Allgemeines Krankenhaus, Vienna | 1878–87 | 11.50 | 12.40 | 25.5 |
| Italian hospitals | 1885 | 10.37 | 11.32 | |
| Bellevue Hospital | 1875–86 | ..... | 12.00 | 30.1 |
| Roosevelt Hospital | 1875–87 | ..... | 10.80 | 27.5 |
| New York Hospital | 1877–88 | ..... | 7.86 | 18.0 |
| St. Luke's Hospital | 1875–88 | ..... | 11.07 | 39.6 |
| City (Boston) Hospital | 1875–88 | ..... | 10.17 | 22.9 |
| Massachusetts General Hospital | 1874–88 | ..... | 8.31 | 26.7 |
| Pennsylvania Hospital | 1874–88 | ..... | 8.88 | 28.1 |
| Cincinnati Hospital | 1875–88 | ..... | 9.26 | 29.3 |
| Rhode Island Hospital | 1875–88 | ..... | 8.91 | 37.4 |

In his prize-essay on "Hospital Statistics" Dr. Steele substantially agrees with the remarks of Dr. Guy above referred to, and says that the hospital which confers the greatest benefit upon the community is that having the highest death-rate, as it is the one which admits the most critical and incurable affections. As the population of a city increases, the demand for hospital accommodation also increases, and, unless more of this is provided, the tendency is to select the more serious cases for admission, and thus to procure an increased mortality-rate.

I cannot assent to the proposition that a high mortality is any proof of the utility of a hospital, or of the skill of its staff—but it is certainly not a proof of the contrary.

The mortality of the non-accident cases averages from four to five per cent. But the fame of the hospital, the reputation of its staff, especially for difficult and hazardous operations, may tend to increase the ordinary death-rate.

An increased mortality in the surgical ward may be due to special provision for permanent residence of patients with incurable disease, such as the establishment of a ward for cancer-cases.

There have been a number of reports and discussions in statistical congresses and societies with regard to the best forms to be used in publishing hospital statistics. The following are the desiderata for hospital statistics as given by Miss Nightingale:

1. Remaining in hospital on the first day of the year.
2. Admitted during the year.
3. Recovered or relieved during the year.
4. Discharged incurable, unrelieved, for irregularities, or at their own request.
5. Died during the year.
6. Remaining in hospital on the last day of the year.
7. Mean duration of cases in days and fractions of a day.

In each of these headings the data are given for each disease, for each sex, and for each of a number of groups of ages; the primary object being to ascertain the total sick population, that is, the number of beds constantly occupied during the year for each disease, and each age and sex; 2, the number of cases of each disease, for each age and sex submitted to treatment; 3, the average duration of each disease for each age and sex; 4, the mortality of each disease for each age and sex; and, 5, the proportion of recoveries for the same.[1]

From what has been said in these lectures it will be seen that no form of hospital statistics can be considered as satisfactory which does not give the distinctions of sex and age, and this not only for the total of all the patients but for each of the several forms of disease treated. The best form for hospital statistics is probably the following:

*Form of Table for Hospital Statistics.*

| | | Total. | AGES. | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | Under 5 | 5–10 | 10–15 | 15–20 | 20–25 | 25–35 | 35–45 | 45–55 | 55–65 | 65–75 | Over 75 |
| Remaining at commencement | M. | | | | | | | | | | | | |
| | F. | | | | | | | | | | | | |
| Admitted during the year | M. | | | | | | | | | | | | |
| | F. | | | | | | | | | | | | |
| Discharged | M. | | | | | | | | | | | | |
| | F. | | | | | | | | | | | | |
| Transferred | M. | | | | | | | | | | | | |
| | F. | | | | | | | | | | | | |
| Died | M. | | | | | | | | | | | | |
| | F. | | | | | | | | | | | | |
| Remaining at end of year | M. | | | | | | | | | | | | |
| | F. | | | | | | | | | | | | |
| Total number of days' treatment | M. | | | | | | | | | | | | |
| | F. | | | | | | | | | | | | |
| Death-rate per total disposed of | M. | | | | | | | | | | | | |
| | F. | | | | | | | | | | | | |

Prior to the discovery and employment of antiseptic methods in obstetrics the records of lying-in hospitals were very unsatisfactory. It is true that we have no very definite standard of death-rates in childbearing in private practice with which to compare them, but this rate is given by the Registrar-General of England as being at the rate of five per thousand children born alive for the twenty-eight years, 1847 to 1874.

The summary of the returns of the extern maternities in connection with Guy's, St. Bartholomew's, and St. Thomas' Hospitals for the twenty-one years, 1856 to 1876, comprising an aggregate of 74,580 cases, gives a mortality of 4.1 per thousand.

The largest lying-in hospital, and the oldest, is that known as the Rotunda, or Dublin Lying-in Hospital. In 198,481 cases of confinement in that hospital, the death rate was 13.9 per thousand.[2] The following table is of interest in this connection:

[1] See paper on Hospital Statistics and Hospital Plans, by Florence Nightingale, Transactions of the National Association for the Promotion of Social Science, 1861, p. 554.

[2] Summarized from Dublin Medical Journal, 1869, and from Dr. Johnston's Annual Reports from 1868 to 1875.

*Table showing, for Prussia, from 1816–86, the Number of Deaths in Childbed, the Proportion per 100 to Labor Cases, to Women between 15 and 45, to Total Deaths, and the proportion per 1,000 of Population.**

| Period. | Number | Per cent. of labor cases. | Per cent. of women, 15-45. | Per cent. of all deaths. | Per 1,000 of population. | 1 death to each case of labor. |
|---|---|---|---|---|---|---|
| 1816–20. | 22,036 | 0.9454 | 18.82 | 1.430 | 0.402 | 1 : 106.0 |
| 1821–30. | 44,826 | 0.8979 | 16.78 | 1.300 | 0.360 | 1 : 101.4 |
| 1831–40. | 48,291 | 0.7982 | 13.61 | 1.160 | 0.345 | 1 : 112.2 |
| 1841–50. | 47,506 | 0.7779 | 12.45 | 1.030 | 0.294 | 1 : 130.2 |
| 1851–60. | 53,341 | 0.7949 | 13.07 | 0.950 | 0.302 | 1 : 127.5 |
| 1861–70. | 64,056 | 0.7716 | 13.99 | 1.070 | 0.304 | 1 : 129.8 |
| 1871–75. | 41,735 | 0.8398 | 14.82 | 1.130 | 0.328 | 1 : 121.2 |
| 1876–86. | 68,942 | 0.5830 | 10.89 | 0.902 | 0.237 | 1 : 167.7 |

* Ehlers Zeitschrift f. Geburtshülfe, etc., 1889, xvi., p. 455.

It is not an easy matter to determine what may be called the normal or average mortality of women in childbirth, in order to determine the probable utility of a particular mode of managing cases of labor, as, for example, the so-called aseptic method. From the mortality statistics of the last United States Census [1] we find that in 1,577,173 births 5,646 deaths of the women are reported, being in the proportion of 3.57 per thousand births. This proportion was higher in the rural districts than in the large cities, and in negroes than in whites, as will be seen from the table:

| | Total births. | Deaths from childbirth. | Deaths from childbirth per 1,000 births. |
|---|---|---|---|
| The United States | 1,577,173 | 5,646 | 3.57 |
| Rural | 1,348,561 | 5,283 | 3.91 |
| Cities | 228,612 | 363 | 1.58 |
| Whites in Southern States | 723,884 | 2,225 | 3.07 |
| Colored in Southern States | 240,607 | 1,217 | 5.05 |

For the same year (1880) the Registrar-General of England reports the death-rate of women in relation to births as 2.07 per thousand. If now we compare these figures with those given by obstetricians and physicians, we shall find that the latter give death-rates from two to four times as great. Thus, Duncan gives the death-rate in private practice as from 8 to 10 per 1,000 births, while LeFort gives the figures from maternity hospitals as 30,594 deaths in 888,312 births, or over 34 per thousand; while Ehlers, using the statistics of Prussia from 1816 to 1886, gives the rate as from 5.8 to 9.4 per thousand.

How are we to explain these differences? Is the reported greater mortality in rural districts, in certain races, or in physicians' reports, due to peculiarity in the cases reported, or to the surroundings, or to the method of making reports and collecting data? Evidently the latter is first to be considered. In the data furnished by the census and the English registration reports, the cases attended only by midwives and wise-women are included as well as those attended by physicians, and it is among the negroes and the Germans that the proportion of cases thus attended is the greatest. Moreover, in the cities where there is a regular registration of deaths upon physicians' certificates there is less tendency to give the vague term childbirth as the cause of death than in the rural districts where the cause of death is returned by non-professional persons; but this does not apply to England, and it is not probable that it greatly influences the results in this country.

The deaths reported in the census as due to childbirth are those which occur during or soon after labor, including those due to hemorrhage, exhaustion, acute uræmia, etc., while those which occur at a later period may be reported as due to peritonitis, septicæmia, etc., although the physician in reporting the results of his private practice would include all these as deaths due to labor.

While the physician will usually consider only the relation between the number of cases of labor and the number of deaths in childbirth, the vital statistician will study the relations of deaths in childbirth to the number of women living between the ages of fifteen and fifty years, or to the total number of deaths from all causes. The figures of the last United States Census show that of every 100,000 women between the ages of fifteen and fifty living in our large cities, 16.21 died in childbirth during the year, while in the rural districts the corresponding figure is 51.58. The following table shows the ratios in relation to deaths of women from all causes, with certain distinctions of locality and race:

*Table showing, for Rural and Cities, for White and Colored Females, and for Females of Irish and German Parentage, the Proportion of Deaths from Childbirth and Abortion in 1,000 Deaths of Females from Known Causes.*

| Grand Groups. | Rural. | | Cities. | | White. | | Colored. | | Irish Parentage. | | German Parentage. | |

| 18. Region of the Western Plains | 33.5 | 5.7 | 5.5 | 5.5 | .... | ... | .... | ... | 100.0 | ... | 75.7 | |
| 19. Heavily timbered region of the Northwest | 19.6 | 3.2 | .... | .... | .... | ... | .... | ... | 28.1 | 1.9 | 52.2 | 1.0 |
| 20. Cordilleran region | 37.0 | 2.7 | .... | .... | .... | ... | . .. | ... | 33.1 | ... | 13.3 | 3.5 |
| 21. Pacific Coast region | 29.8 | 1 7 | 3.7 | 1.0 | .... | ... | .... | ... | 33.7 | ... | 15.4 | |
| Total | 19.5 | 2.3 | 4.7 | 1.2 | 13.9 | 0.9 | 24.8 | 1.4 | 14.1 | 0.5 | 18.3 | 0.8 |

If, then, we are to judge as to whether the death-rate in childbed in the practice of a particular physician is to be considered as high or low, we must first know whether the figures relate to hospital or to private practice, and, if the latter, whether it was in the city or in the rural districts. To obtain some standards for comparison we may use the numerous reports found in medical literature in which physicians have given the statistics of their private obstetrical practice, and compare the results with those given in the statistics of maternity hospitals, for which purpose the table on top of page 650 will be found of interest.

Suppose that for the sake of testing the relative efficiency of two different modes of treatment, or of the general progress made during a series of years in therapeutics, we take the statistics of a particular disease; which should be one having a tolerably definite train of

* For prisons and asylums the death-rates should be given for the average daily population in the institution, and not for the number of admissions or for the number of cases disposed of; but in these cases gross death-rates for the whole population are of very little use. It is necessary to have them with distinction of sex and age in order to make comparisons with the death-rates of the general population coming under the same groups.

symptoms, so as to be easily recognized. A disease which it is common to select for this purpose is acute lobar pneumonia. Suppose, now, that in a given group of cases of pneumonia subjected to one method of treatment the mortality is found to be greater than in another series of cases subjected to a different treatment, are we thereby authorized to conclude that that mode of treatment connected with the lowest mortality is really the cause of the low mortality? By no means. Before we can do this, we have to settle the character of the cases, the proportion of those in each group occurring in advanced age, or in intemperate persons, or in those affected with other diseases, or in certain races, because all these circumstances influence the death-rate. We have also to take into account the total number of cases in each group, in order to make an allowance for the probable error due to small numbers. If the two groups of cases have occurred in different localities, or have been treated in different institutions, we have then to take into account the special influences of the locality or institution, as far as it is possible to do so, and not until all these corrections have been made can we fairly estimate the relative influence of the treatment.

I have collected the statistics of 209,755 cases of pneumonia occurring in this country and in Europe within the last fifty years, as shown by the following table, giving an average death-rate of 21.11 per cent. The distinction of sex is given in 33,904 of these cases, showing a death-rate of 19.86 per cent. in males, and 24.68 per cent. in females.

| | Cases. | Deaths. | Percentage of mortality. |

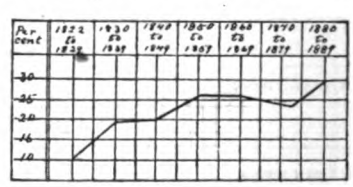
| Civil hospitals, females | 11,042 | 2,726 | 24.68 |
| Total | 33,904 | 7,265 | |

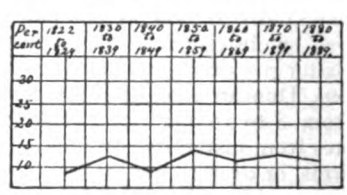
The distinction of deaths by ages for each sex is given in 24,557 cases, and from these data I have calculated the proportion of deaths to cases in each age-group, as shown by the table and diagram on opposite page. The immense importance of age as a factor in the death-rate from this disease is at once apparent.

In the absence of statistics of cases and deaths by ages, we can get very little information from statements of death-rates from pneumonia. For example, the death-rate in the United States Army hospitals from pneumonia from 1877 to 1888 was 18.72 per cent. of the cases treated. Was this a high or a low death-rate? We can only say that it was probably rather below the average, since the average death-rate for males between twenty and fifty years of age is 19.9 per cent. on cases treated. The need of such considerations is well illustrated in a paper by Drs. C. W. Townsend and A. Coolidge, contained in the *Medical News*, July 27, 1889, page 85.

This paper is a discussion of all the cases of acute lobar pneumonia treated at the Massachusetts General Hospital from 1822 to the present time, the figures being divided into periods of ten years, making seven decades in all. The following chart indicates the gross result in



1,000 cases. This would indicate a steady rise in fatality from 1822 to the present time. What are the circumstances which make the cases of pneumonia coming into the hospital during the last few decades more fatal than those which occurred during the first three or four decades? One of the first things investigated was the average ages of the cases of pneumonia admitted in each decade, and the results obtained showed that there was a greater number of patients over fifty years of age in the latter decades, and that the average is steadily increasing. In like manner, the proportion of cases occurring in persons of intemperate habits, or complicated with other diseases, was examined for each decade. The influence of race was also estimated, with the result that in Americans nine per cent., in Irish eleven per cent., and in other foreigners



fourteen per cent. were fatal; this was omitting all fatal cases over fifty years of age who were intemperate or complicated. Now if we take the mortality and make the necessary corrections for the influence of age, or proportion of intemperate and complicated cases, we get the above diagram.

*The Proportion of Deaths to Cases in Age-Groups.*

| | Cases. | | | Deaths. | | | Deaths by Ages to Cases by Ages per 100. | | | Cases by Ages to Total Cases per 100. | | | Deaths by Ages to Total Deaths per 100. | | |

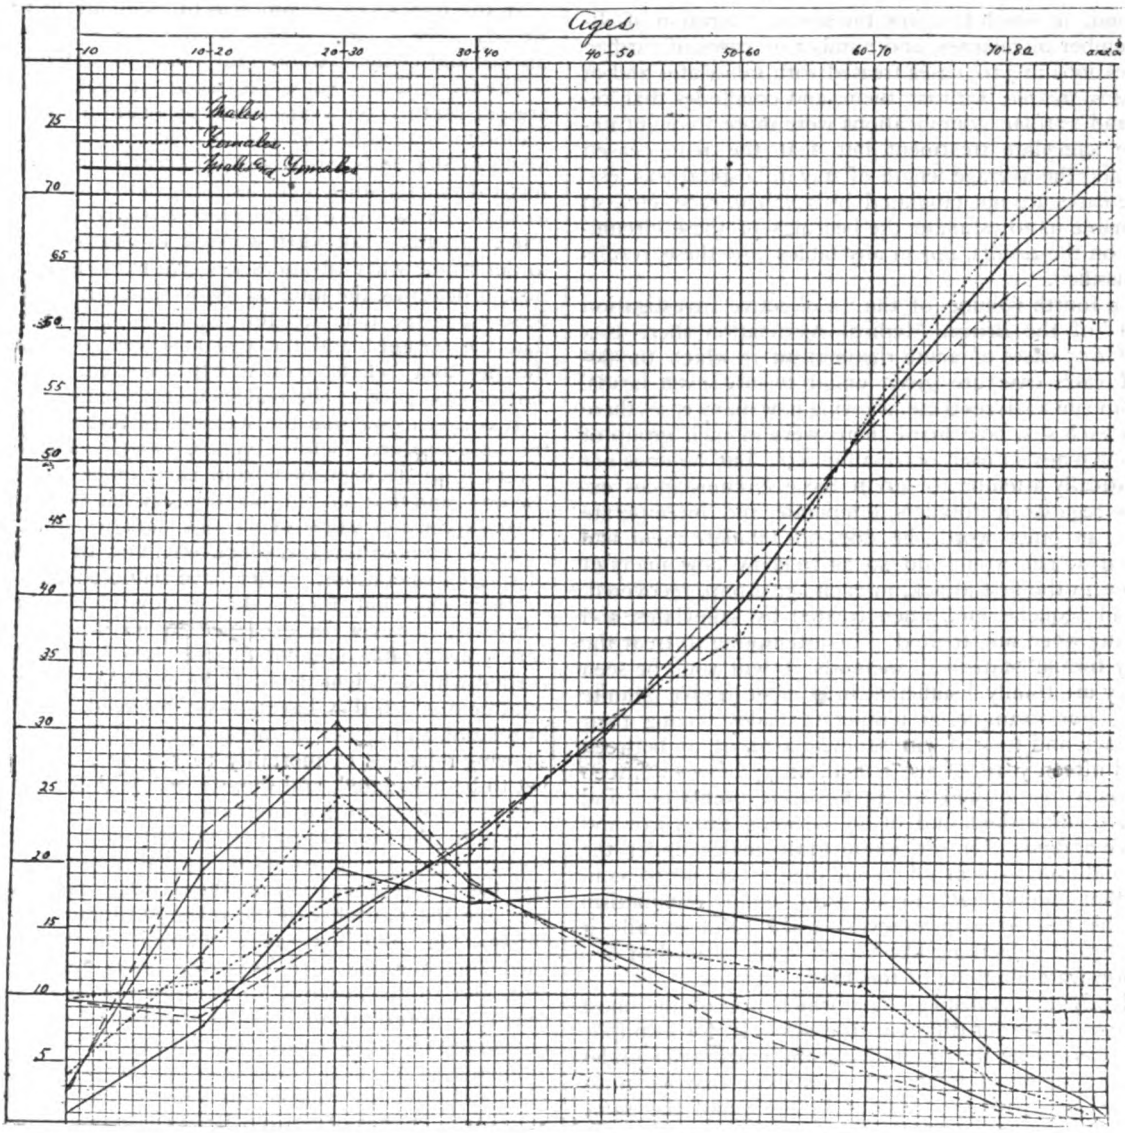
*Diagram Showing by Sex and Groups of Ages for* 24,557 *Cases of Pneumonia.*



— — — The ratio, per 100, of deaths, at each group of ages, to cases at same age. - - - - - - The ratio, per 100, of cases, at each group of ages, to total cases. —— —— The ratio, per 100, of deaths, at each group of ages, to total deaths.

Here, then, when we set apart the influence of the causes of death which are entirely independent of treatment, we find that there is but little variation of mortality from decade to decade, and if the influence of race were brought in, we could not infer that, upon the whole, there had been any material change in the mortality of pneumonia for the last sixty-eight years, although there have been very great variations in the treatment during that time.

The conclusions arrived at by the authors are as follows :

1. In the 1,000 cases of acute lobar pneumonia treated at the Massachusetts General Hospital from 1822 to 1889 there was a mortality of twenty-five per cent.

2. The mortality has gradually increased from ten per cent. in the first decade to twenty-eight per cent. in the present decade.

3. This increase is deceptive, for the following reasons, all of which were shown to be a cause of a large mortality :

*a.* The average age of the patients has been increasing from the first to the last decade.

*b.* The relative number of complicated and delicate cases has increased.

*c.* The relative number of intemperate cases has increased.

*d.* The relative number of foreigners has increased.

4. These causes are sufficient to explain the entire rise in the mortality.

5. Treatment, which was heroic before 1850, transitional between 1850 and 1860, and expectant and sustaining since 1860, has not, therefore, influenced the mortality rate.

6. Treatment has not influenced the duration of the disease or of its convalescence.

Suppose we try to estimate the relative value of a particular treatment of rheumatism—say, by salicylates. We find several tables in medical literature giving the results, treated by this and other methods. As a type, take the analysis of 1,200 cases treated at Guy's Hospital given by Dr. Hood,[1] in which he gives the average duration of illness, number of relapses, and number of cases of cardiac complications in 350 cases treated with salicylates and in 350 cases treated without them, and concludes that relapses and cardiac complications were more frequent under the salicylate treatment, but that the pain ceased sooner and the average length of stay in hospital was less. But the cases are not tabulated by sex, age, race, etc., so as to enable us to estimate the bearings of these circumstances on the results, nor in any tables are these results thus classified.

In the fourth volume of the "Collective Investigation Record" of the British Medical Association there is a table of 655 cases of acute rheumatism in which the details of each case are given under twenty-seven heads. Dr. Whipham analyzes these, showing how many cases there were in each sex, how many there were in each group of ages, how many in each occupation, etc., but he does not systematically attempt to group these circumstances except as regards teetotallers, temperate and intemperate persons; in other words, he does not tabulate them as a vital statistician would do so as to show how many of each sex in the first attack, in each age-group, recovered, died, had sequelæ, etc., when treated by salicylates, and how many when not treated. In attempting to treat the data by formal statistical methods it will soon be seen that they are totally insufficient in number to give definite results. For example, in temperate males having their first attack and treated with salicylic acid, of 25 between five and fifteen years of age 1 died, of 77 between fifteen and twenty-five 1 died, of 35 between twenty-five and thirty-five none died, and of 17 between thirty-five and forty-five 2 died. Of the intemperate males under the same conditions—16 in all—none died. Are we to conclude that intemperate males with acute rheumatism should be treated with salicylic acid? Not at all—it would require something like 60,000 cases instead of 600 to demonstrate anything of this kind.

Evidently the statistical data which are of the most importance differ for different diseases. If, for example, we are comparing the mortality from pneumonia under different systems of treatment, it is clear that we must have the data with subdivisions by age; and the same would hold good for Bright's disease, and, in fact, for almost all diseases, if the law of decline of vital energy with advancing years holds good. But for cancer the data of sex and race are quite as important as those for age.

An important point in medical and vital statistics is to keep the current record, or what may be called the day-book account, entirely separate and distinct from the classification or modes of tabulation. The current record must be made complete at the time, for if any items are left out they can never be replaced. But this record, once made, may be used in various systems of classification and comparison for many years afterward. If an attempt be made to put this record into the form of a classified return primarily, it is certain to be defective and will not be applicable to researches of another kind.

NOTE.—In attempting a collective investigation for the purpose of securing medical statistics everything depends upon the questions asked, and there are exceedingly few men who are competent to prepare them. As an example of how not to do it, take a set of questions adopted by a certain medical society for investigation (Middlesex East (Mass.) District Medical Society. See *Boston Medical and Surgical Journal*, vol. lxviii., 1863, p. 345). For example, "Bromide of ammonium in atheromatous affections and obesity. Dose, five grains thrice daily." "Iodide of ammonium as a substitute for iodide of potassium; said to have a more absorbent power," etc. "Galium aparine. In epilepsy. Dose, one fluidrachm thrice daily," etc.

In the reviews of the progress of medicine, of which we already have a large supply in the shape of annual addresses and centennial literature, and to which extensive additions will no doubt be made at the close of the present century, ten years hence, you will find more or less elaborate statements of the advances which have been made in diagnosis, pathology, preventive medicine, and surgical therapeutics in all its branches. Also, it is easy to show that we have made great advances in the art of relieving pain. But when we seek by statistical methods to determine what advances we have made in the prevention of death by the internal use of drugs, it must be confessed that the data are, for the most part, wanting, and that the optimist and the pessimist can propound their theories and beliefs upon nearly an equal footing, *i.e.*, that of ignorance of the real facts in the case.

It is easy to see that the statistics of fevers collected in the last century, before typhus, enteric, and relapsing fevers were distinguished from each other, are of little use now, and that modern bacteriology has destroyed, to a great extent, the value of the old statistics of tubercular diseases, typhoid fever, cholera, etc., and of the statistics of surgical operations. They have rendered some service in their day, but their value is now chiefly historical. There is, however, in existence in medical literature a very considerable number of cases which have been recorded with sufficient detail to be available for statistical treatment which they have not yet received. Death-rates in relation to number of cases of special forms of disease showing relations of mortality to sex, age, and race, are yet to be calculated, and there is material for some good and useful work in this direction.

Within the last twenty-five or fifty years, in civilized communities, the gross mortality has diminished, there has been a prolongation in the average expectation of life, and the mortality of the years of infancy has greatly diminished. But how much of this is due to preventive medicine, how much to improved conditions of habitation and to the lowering of the price of food, and how much to improved methods of treatment? Dr. Sweifel endeavored to answer this question in a lecture on "The Influence of Medical Knowledge on the Life of the People," delivered in Leipsic in 1887 ("Der Einfluss der ärztlichen Thätigkeit auf die Bevölkerungsbewegung").

Taking, as a basis for his calculations, the figures of Bavaria for ten years, and those of Saxony for thirteen years, he found that for 100,000 living population the average number of deaths from tuberculosis increased from 250 to 258; from inflammation of the lungs, from 222 to 270; from croup and diphtheria, from 98 to 123. He remarks that these are saddening figures. In spite of the sanitarians and health-resorts, in spite of ventilation, new methods of treatment by inhalation, compressed air, etc., the number of men who die from diseases of the respiratory organs is steadily increasing, and he queries whether Süssmilch was not right in his phrase "göttliche Absterbeordnung," divine law of death.

On the other hand, he shows that the mortality from

[1] British Medical Journal, December 31, 1881, p. 1119.

typhus has fallen from 62 to 34. But the question is, whether this is due to diminished prevalence of the disease or to a diminished mortality in the same number of cases of the disease due to improved medical treatment. It may be noted in this connection that the chief effect of improved sanitation appears in the lessened mortality in children under five years of age, and that it is chiefly in the mortality occurring after these ages that we are to look for the influence of improved medical treatment. In examining this, however, it is to be remembered that improved sanitary conditions affecting chiefly infants, by preserving a number of feeble and sickly children, tend to produce a higher rate of mortality in succeeding years. In cases admitting of surgical treatment, and in childbirth, there can be no doubt as to the diminished mortality in the practice of those who use the best accepted modern methods; but these methods are not yet used scientifically by half of the profession, and the results are not perceptible in the general death-rates thus far collected.

It must be admitted that the greater part of the increased expectation of life is probably due to better food, purer water, greater cleanliness, and improved methods of preventing the spread of contagious diseases. If we look at the curves representing the loss of life in large masses of people at different times and places, we see that the laws of life and death have but a narrow range of variation after the age of infancy has passed, and that improvements in therapeutics have lifted the lines but very little. They have lessened suffering greatly, but they have not greatly deferred death.

In our present state of knowledge there are certain forms of disease and derangement of organs whose tendency is to recover without any treatment, or in spite of bad treatment. There are also certain diseases and derangements which are incapable of cure by any known method of treatment. Otherwise, man would not be mortal. Between these two classes is a small number of cases of disease the result of which depends on the treatment. In order that medical statistics may give us any information in regard to this last class we have got to have some idea as to the proportion of each of the two other classes.

Out of the 756,803 deaths reported in the United States in the last census year, 355,575 were of persons of twenty years of age and upward. The above table shows the proportion of these deaths which were due to sixteen groups of causes, which produced in all eighty-five per cent. of them, and the proportions due to each of these is indicated by the diagram before you.

I leave it to you to say for which of these diseases, or classes of disease, it is most likely that progress is to be made in the line of prevention, and for which we have the best reason to hope for improved methods of cure after they are once established.

*Total Deaths from Known Causes over Twenty Years of Age* = 346,280 (*Census of* 1880).

| | Deaths per 1,000 of deaths from known causes at twenty years of age and over. | Deaths over twenty years of age (unknown deducted). | Deaths per 10,000 of population of twenty years of age and over. |
|---|---|---|---|
| Consumption | 217.64 | 75,367 | 28.94 |
| Pneumonia | 106.35 | 36,827 | 14.14 |

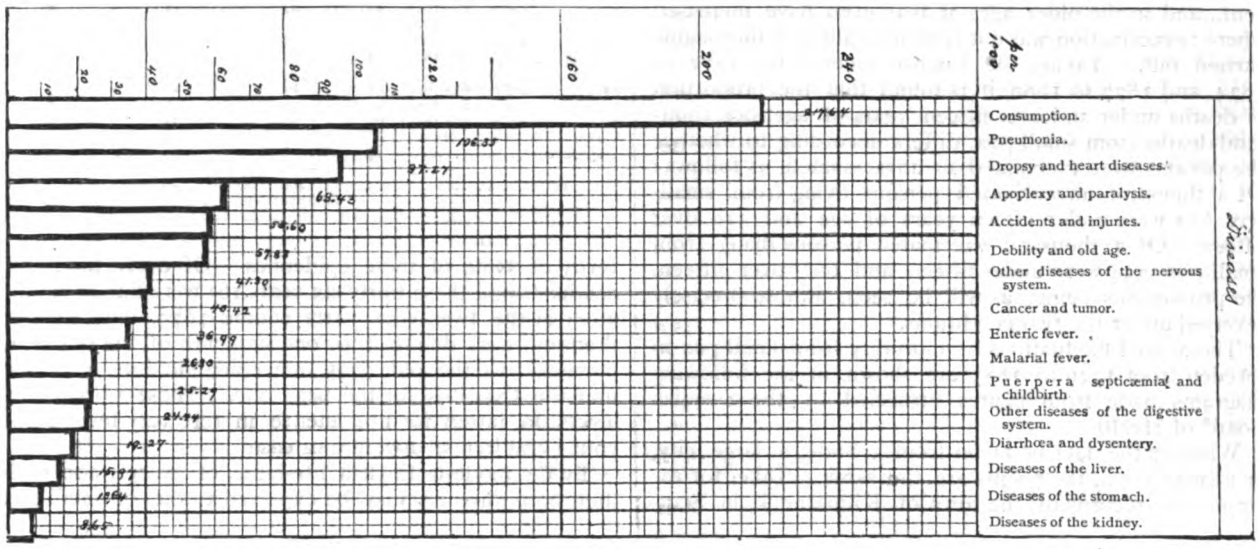
*Diagram showing Proportion of Deaths from Specified Diseases to* 1,000 *of Total Deaths from Known Causes of Adults, Twenty Years of Age and over* (*Census of* 1880).



A very good illustration of some of the ways in which lies can be told with statistics may be found in the various books and papers which have been produced in connection with the anti-vaccination controversy.

In order to understand the relations between vaccination and small-pox, it is necessary to have the death-rates from small-pox given for different periods of life—that is, by age. In this country and in Great Britain we have no data as to the deaths by small-pox by different ages prior to the introduction of vaccination, because the registration of deaths by ages has only been carried on for a little over fifty years. We can, however, for Great Britain, compare the statistics of vaccination for three different periods—the first from 1847 to 1853, in which gratuitous vaccination was provided for the people, but it was purely an optional matter with them whether they should make use of it or not; from 1854 to 1871, vaccination was obligatory by law, but this was mainly theoretical, since the law was practically not enforced; from 1872 to 1880, when the vaccination was rigidly enforced.

The table on top of page 654 shows the results of this difference.

Before the introduction of vaccination there were but few persons who did not have the disease at some time in their lives. It appeared in epidemic waves over Europe, usually at intervals of from five to seven years, being about the period of time required to accumulate, by

*Mean Annual Deaths from Small-pox at Successive Life Periods, per 1,000,000 living at each Sub life Period.*

| Sub-period. | AGE. | | | | | | |
|---|---|---|---|---|---|---|---|
| | All ages. | 0— | 5— | 10— | 15— | 25— | 45 and upward. |
| 1. Vaccination optional (1847–53) | 305 | 1,617 | 337 | 94 | 109 | 66 | 22 |
| 2. Vaccination obligatory but not efficiently enforced (1854–71) | 223 | 817 | 243 | 88 | 163 | 131 | 52 |
| 3. Vaccination obligatory, and more efficiently enforced by vaccination officers (1872–80). | 156 | 323 | 186 | 98 | 173 | 141 | 58 |
| Entire period of obligatory vaccination (1854–80) | 198 | 633 | 222 | 92 | 167 | 135 | 55 |

births, a sufficient amount of susceptible persons to enable an epidemic to make headway. Of course, then, the great majority of persons had the disease in infancy, or in early childhood, and a large proportion of these died. So that in those days the small-pox mortality, in the early years of life, was high, while those who survived were either protected from future attacks or presented a certain amount of immunity to the poison of the disease, so that the small-pox death-rate of the higher ages was then low. When vaccination came to be general, the young were protected, but were not protected as permanently and completely as would have been effected by an attack of small-pox. The result of this was that the death-rate from small-pox under five years of age fell eighty per cent., while from five to ten years of age it fell forty-five per cent., and in the older ages it may even have increased where revaccination was not systematically and thoroughly carried out. Taking the English records for 1872 to 1874, and 1877 to 1880, it is found that the proportion of deaths under and over fifteen years of age, per thousand deaths from small-pox, differs according to whether the persons were vaccinated or unvaccinated, as follows: Of a thousand unvaccinated persons dying from small-pox 672 were under fifteen years of age and 328 over fifteen. Of a thousand vaccinated persons dying from small-pox 334 were under fifteen and 666 over fifteen, the proportions being, as will be seen, almost precisely reversed under the two conditions.

The annual fluctuations of mortality from small-pox in Sweden from 1749 to 1883 are shown in the following diagrams made from figures furnished by the Swedish Board of Health.

Whether the data be taken from a State, a large city, or a small town, the results are the same. Take, for example, the records of the town of Kilmarnock, in Scotland. For thirty six years, from 1728 to 1764, this place had an average population of 4,200, and a very accurate register of the births and deaths was kept. During these thirty-six years there were nine epidemics of small-pox, succeeding each other at regular intervals of about four years—just the time required to raise a fresh crop of unprotected victims sufficiently numerous to spread the contagion. The following table will give an idea of the severity of some of these epidemics. Of every thousand deaths during these thirty-six years 161 were due to small-pox; in the twenty-six years ending 1879, only 9.9 per thousand were due to it, or one-sixteenth of the old proportion. In the old days one epidemic left very few unmarked victims for the next one. Those who recovered were pitted for life, and there were very few except young children who were unscarred.

| Date of epidemic. | Interval since height of former epidemic. | Total deaths. | Deaths in children born since height of former epidemic. | Deaths in children who had passed safely through one epidemic. | Deaths in individuals who had passed through more than one epidemic. |
|---|---|---|---|---|---|

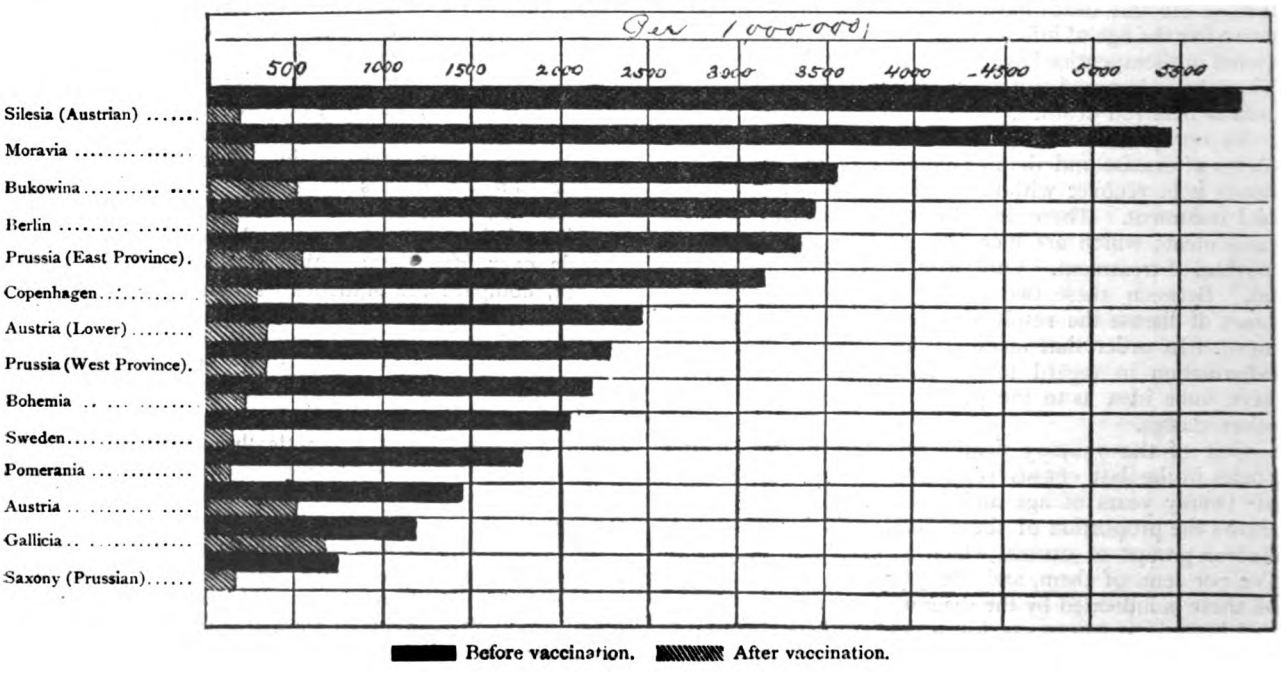
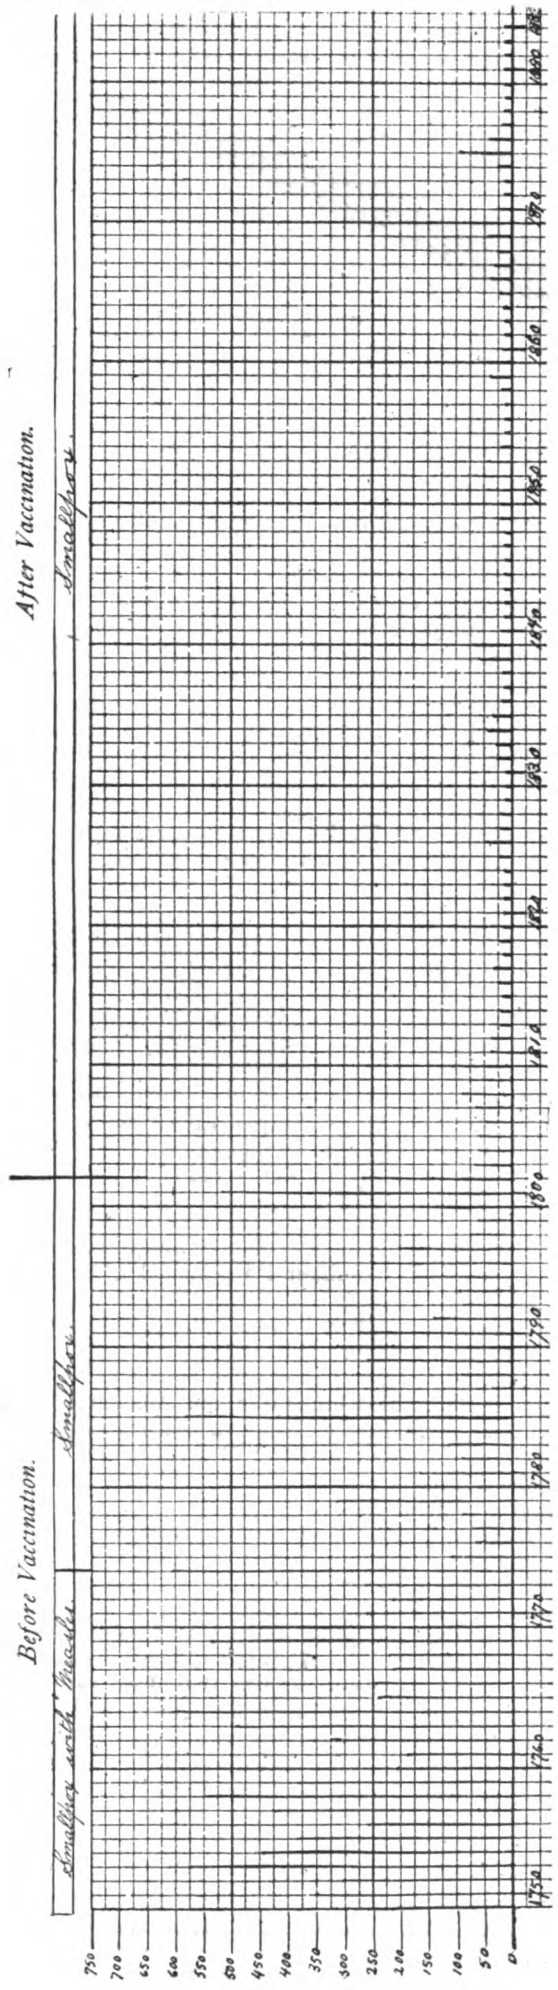
By the modern English life-table, of every 1,000 children born alive 2.3 may be expected to die of small-pox

*Diagram showing for Different Countries, etc., the Approximate Average Annual Death-rate from Small-pox per 1,000,000 of Living Population Before and After the Introduction of Vaccination.*





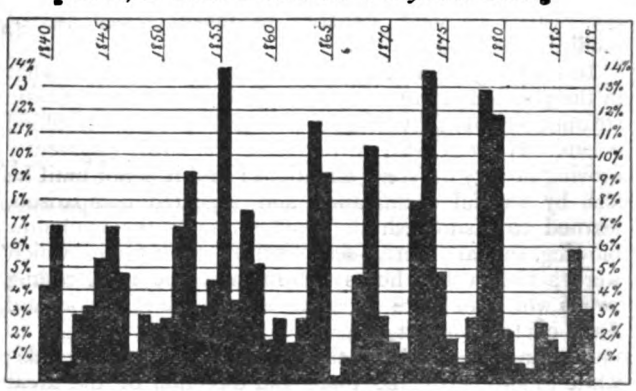
before reaching five years of age. In the old Kilmarnock table the proportion was 116 to every 1,000.

If you compare the death-rate per thousand of living population in an epidemic of small-pox occurring in a city in the United States in recent times with that of an epidemic occurring in a city in the last century, you will probably find that the death-rate was greater in the modern city than in the ancient one. Perhaps two-thirds of the people in the modern city were properly vaccinated—in the ancient city none were vaccinated. Are we to conclude that partial vaccination increases the death-rate from small-pox? Yes, for a single epidemic year; but if you take a period of twenty years or more for your comparison, you find the death-rate much lower in the vaccination than in the ante-vaccination period. Why is this? Because in the ante-vaccination period the adults had been through several epidemics of small-pox, and had either had the disease and survived, or had proved insusceptible to the virus, being, in either case, protected. The only class of the population in much danger from small-pox in those days were the young children born since the last epidemic, less than ten years before. But in the modern community, partially protected by vaccination, there has accumulated a considerable number of unprotected adults during the long periods which now elapse without an outbreak, and these increase the fuel for flame, and consequently the death-rate. Comparisons of small-pox statistics for single years are therefore almost worthless.

The results of vaccination may be indicated in another way: At the commencement of its organization, in 1761, the Equitable Society for Insurance of Lives, the oldest and most important of life-insurance companies, charged 12½ per cent. extra for all persons who had not had the small-pox. In 1781 this was reduced to eleven per cent. extra.

In 1802 it was resolved "that the directors be empowered to grant policies of assurance upon the same terms to persons who aver in their declaration that they have had the cow-pox, as to those who aver in their declaration that they have had the small-pox. But if such person shall die afterwards of the *small-pox*, then such policy shall be void." In 1823 the words, "but if such person shall die afterwards of the small-pox, then such policy shall be void," was stricken out.

*Percentage of Deaths from Scarlet Fever, Providence, R. I., in Total Deaths for Forty-nine Years.*

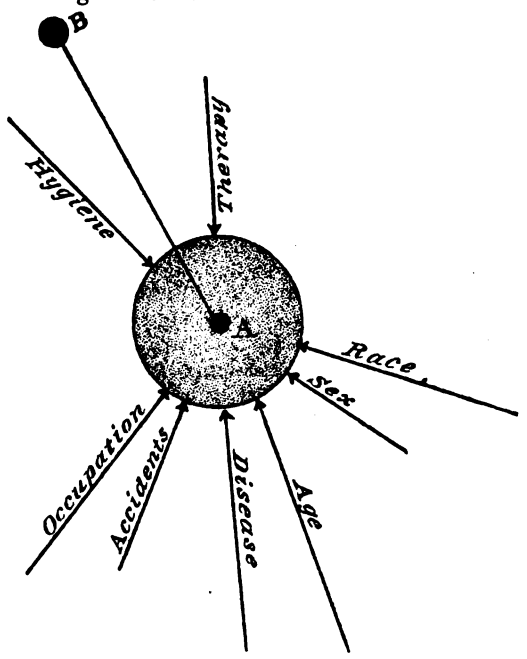


This somewhat irregular periodicity in the appearance of these contagious diseases, of which one attack affords more or less protection against a subsequent attack, is shown not only in these diagrams of the prevalence of small-pox, but also from other similar diseases; as, for instance, in scarlet fever, as shown by the diagram before you, which indicates the percentage of deaths from this cause to the total deaths occurring in Providence, R. I., for each of forty-nine years. You will see that the epidemics occur irregularly at intervals of about five or six years, with somewhat greater mortality at intervals of about ten years.

In vital statistics, as in other branches of social science,

it is not true that the effects of causes acting in combination are equal to the sum of the effects of each of the causes acting separately. Different causes of death having no relation to each other do not have a joint effect which is equal to the sum of the effects of each cause taken separately, and it is therefore difficult to bring the phenomena of vital statistics within the boundaries of mathematical formulæ. In the doctrine of this kind of averages time and number are not convertible terms.

Statistics apply to masses of men, to communities—not to individuals. We find a mass of matter moving in a certain direction with a certain velocity, and endeavor to calculate the direction and amount of the forces which have produced this result. In like manner we may consider the tendency to death in a community as a resultant of several forces as indicated in the diagram, and endeavor to estimate the influence of each of these forces in producing the result.



It is evident that we can know little of the influence which hygiene or therapeutics have had in shortening the line A B, if we know nothing of the length and direction of the other lines of force, and hence we must have the conclusions of vital statistics to make proper use of medical statistics.

In studying medical and vital statistics one is somewhat in the position of a man on the deck of a large Atlantic steamer out of sight of land and gazing on the troubled ocean. He sees many waves, large and small, apparently moving in very different directions; and it is not until he has, by careful examination and repeated comparison, learned to distinguish the ripples due to the wind now blowing, the larger cross-seas resulting from forces which were acting a few hours before, and the long, rolling swells which indicate to some extent the direction and force of the tempest of yesterday, that he can begin to understand the roll of the ship on which he stands; while to appreciate the force and direction of the great current which is sweeping with it all the troubled water and the ship itself, requires skilled observation with special instruments, and the use of charts which embody the experience of hundreds of voyages. So also in viewing the records of human life, disease, and death, the variations which are at first most perceptible are often those which are most superficial, and which give little or no indication of the magnitude and direction of the movement of the great masses beneath.

*Appendix.*

The most valuable sources for data relating to vital statistics, and in many respects to medical statistics also, are those contained in the "Reports of the Registrar-General of England" for the last forty years, and especially in the supplement volumes which have been issued every ten years during that period. Next to these, for matters relating to this country, come the statistics of the State of Massachusetts for the last forty years, the statistics of New Jersey for the last ten years, the mortality and vital statistics of the Tenth Census, and the statistics of Boston, Philadelphia, New York City, and of the District of Columbia. Especially valuable, also, are the vital statistics of Sweden, of Belgium, of Italy, as published for the last six or seven years; of Norway, of Switzerland, of Prussia, and of many of the large cities of Western Europe.

The following works will also be found useful for reference:

Süssmilch, J. P.: Die göttliche Ordnung in den Veränderungen des menschlichen Geschlechts, aus der Geburt, dem Tode und der Fortpflanzung desselben erwiesen, 2 Theile. Vierte verbesserte Ausgabe, genau durchgesehen und näher berichtigt von Christian Jacob Baumann. 8vo. Berlin, 1775.

Niles, N., Jr., and Russ, J. D.: Medical Statistics; or, A Comparative View of the Mortality in New York, Philadelphia, Baltimore, and Boston, for a Series of Years: Including Comparisons of the Mortality of Whites and Blacks in the two former Cities; and of Whites, Free Blacks, and Slaves in Baltimore. 8vo. New York, 1827.

Neison, F. G. P.: Contributions to Vital Statistics, being a Development of the Rate of Mortality and the Laws of Sickness, from Original and Extensive Data; with an Inquiry into the Influence of Locality, Occupations, and Habits of Life on Health; an Analytical View of Railway Accidents; and an Investigation into the Progress of Crime in England and Wales. Third edition, 4to. London, 1857.

D'Espine, M.: Essai analytique et critique de Statistique mortuaire comparée, renfermant les Monographies étiologiques des Accidents et de la plupart des Maladies mortelles, et expliquant les Lois générales de la Mortalité des Peuples par les Influences combinées des diverses Causes de Mort. 8vo. Genève, 1858.

Bertillon: La Démographie figurée de la France, ou Étude statistique de la Population française, avec Tableaux graphiques traduisant les principales Conclusions. Mortalité selon l'Age, le Sexe, l'État-civil, etc., en chaque Département, et pour la France entière, comparée aux Pays étrangers. Folio. Paris, 1874.

Ollendorff, A.: Die periodischen Sterblickeits-Schwankungen in ihrer Bedeutung für die Medicin, Arch. f. path. Anat., etc. Berlin, 1886, cv., 110–128, 1 pl.

Bertillon, Jacques: Article "Démographie" in Encyclopédie d'Hygiène et de Médecine publique. 8vo, tome 1, p. 119. Paris, 1889.

In addition to the census and registration records we have another important source of information in vital statistics, namely, the records of life and health insurance companies. These are not as well known to physicians generally as they should be, and I wish, therefore, to call special attention to the two most valuable compilations of them now in existence, namely, the "Insurance Cyclopædia," commenced by Cornelius Walford, of which five volumes have now been published; and the "System and Tables of Life Insurance based on the Experience of thirty American Life Offices," by Levi W. Meech, published in 1881.

# TUBERCULOSIS OF AN ARTERY, ILLUSTRATING ONE OF THE MODES OF DISSEMINATION OF TUBERCLE BACILLI IN THE BODY.

Being a Specimen Presented at a Meeting of the New York Pathological Society, June 12, 1889.

By JOHN S. ELY, M.D.,
NEW YORK.

Even before the discovery of the tubercle bacillus, in 1882, considerable attention had been directed to endeavors to explain the mode of dissemination of the supposed poison of tuberculosis throughout the body. Belief in organized specific virus as the probable cause of infectious disease had been steadily growing since the study by Davaine of the bacillus of anthrax, and in 1878 this belief received most substantial support from the investigation of Koch into the nature of the infectious diseases of wounds. It is therefore quite natural that many investigators should have been at work upon the various problems connected with the etiology of tuberculosis, most of them imbued with belief in the existence of some specific organism as its exciting cause. As has been said, one of these problems had to do with the mode of dissemination of the virus in the body, more especially in cases of acute miliary tuberculosis. The fact that, even before the discovery of the specific virus, a rational and accurate description of at least one way in which this may occur had been offered, is striking demonstration of the usefulness of careful study of the lesions of the infectious diseases, even though for a time all attempts to discover their specific micro-organisms may be vain. Let us hastily glance at some of the more important steps in the proof that, in most cases of acute miliary tuberculosis, it is through the medium of the circulation that the infectious material finds dissemination.

In 1879 it was shown by Mügge [1] that in acute miliary tuberculosis of the lungs it was not uncommon to find miliary tubercles on the intima of small veins in the lung. In nine out of ten cases examined, he succeeded in demonstrating their presence. During the same year Weigert [2] published reports of three cases of acute miliary tuberculosis, in which old foci of tubercular inflammation which had undergone cheesy degeneration were found to have extended to large veins at the root of the lungs, setting up in them tubercular phlebitis. He drew attention to the ease with which large quantities of cheesy matter might, in such cases, find entrance into the circulation. The next year, in the study of a case of tubercular meningitis, Cornil [3] observed small tubercles in the intima of many of the meningeal vessels; and a little later, Kiener [4] repeated this observation in the case of other serous membranes. In 1882, only a short time before the publication of Koch's discovery, Weigert [5] added a series of most instructive cases to those published in 1879, in which he found abundant substantiation of the conclusions then drawn. In six of the cases acute miliary tuberculosis was shown to have resulted from infection of the blood from large vein tubercles, and in two cases the thoracic duct was found to have been the point of entrance of the virus into the circulation. In both of these Weigert was able to discover small tubercles on the intima of veins in various parts of the lungs. The next year he [6] reported the finding of tubercle bacilli in the lesions of all these cases.

In 1883 we begin to have accounts of the finding of tubercle bacilli in the blood. The first of these we owe, I believe, to Babes and Cornil.[1] In 1884 similar observations were made by Weichselbaum [2] in three cases of acute miliary tuberculosis. The same year Lustig [3] applied the knowledge gained from these investigations to diagnostic uses, finding tubercle bacilli during life in the blood of a patient in whom the diagnosis of acute miliary tuberculosis had been suspected, but could not otherwise be proved. In 1885 these observations were confirmed by Ulacacis,[4] Sticker,[5] Rütimeyer,[6] and Doutrelepont.[7]

Up to the time of which we are speaking, it was as the result of involvement of veins, more especially, that infection of the blood was supposed to occur. In 1886 Weigert [8] showed that this is by no means always the

Fig. 1.—Tubercular Arteritis, the Result of the Encroachment of an Area of Tubercular Inflammation upon an Artery in the Lung. (From Delafield and Prudden's "Handbook of Pathological Anatomy.")

case; that arteries are often seriously compromised by surrounding tubercular masses. He reported at the same time the case of a child, four years of age, in whom this had led to the production of acute miliary tuberculosis. He was almost immediately confirmed in this by Nasse [9] and Durand-Fardel,[10] both of whom found, in addition,

miliary tubercles on the intima of small arteries in the kidneys.

Tubercular endocarditis was described during the same year by Heller,[1] in a paper read before the Congress of German Naturalists and Physicians at Berlin.

This, then, completes the proof, for these observations have been repeatedly confirmed. We have seen that veins, arteries, and thoracic duct have been observed to be involved in masses of tubercular tissue; that miliary tubercles have been found in the intima of veins and arteries throughout the body, and in the endocardium; that these lesions have all been found to contain tubercle bacilli; and, lastly, that tubercle bacilli have been found in the blood in cases of acute miliary tuberculosis, both during life and after death.

The specimen which I present to-night illustrates one of the modes in which infection of the blood may occur. It is a section of the upper lobe of the left lung of a child who died of acute miliary tuberculosis. Autopsy revealed very large and cheesy bronchial glands, and scattered through both lungs were many miliary and submiliary tubercles. At the apices and in the vicinity of the bronchial glands cheesy masses of conglomerate tubercle were found. But what is of especial interest is the encroachment of many of the tubercles upon the walls

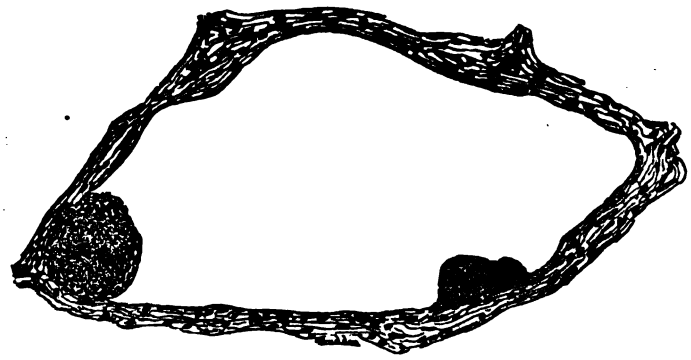

FIG. 2.—Dr. Northrup's Specimen illustrating Vein Tubercle.

of blood-vessels. In places the walls of veins are affected; in others those of arteries. The most beautiful of these, and the one to which I desire to direct attention more especially, is a small artery near the base of the upper lobe, which is encroached upon by a miliary tubercle immediately adjoining it, and in which a tubercular arteritis is seen. The wall of this vessel is infiltrated with small round cells, and, projecting into its lumen, and partially occluding it, is a mass of small round cells, in the centre of which cheesy matter is distinctly visible. It will readily be appreciated how slight a variation in arterial pressure might be sufficient to cause this degenerating mass to be thrown into the circulation, and carried by it to any part of the body. The accompanying drawing (Fig. 1), made from the specimen by Dr. Prudden, represents the condition which I have endeavored to describe.

Tubercle bacilli have been found in these lesions in other sections from the same lung.

In conjunction with the specimen of tubercles in a vein just presented by Dr. Northrup, these specimens are an interesting corroboration of the theory whose development I have endeavored to trace; the first (Dr. Northrup's, Fig. 2) showing the effect produced by the lodgement of tubercle bacilli on the intima of a vein, one of the ways in which they may have entered the blood-current being exemplified by the second.

## SLOW PULSE.

BY NATHAN MAYER, M.D.,

HARTFORD, CONN.

THIS sketch describes, in its main features, a case of very slow pulse, and hazards some diagnostic opinions in regard to it. The subject is not one of wide practical applicability, but it is one of exceeding interest as far as the causation and prognosis are concerned.

A man, aged sixty-five, who has not been sick for fifteen years of aught save the chance minor disturbances of an every-day life, complained one day of œdema of the right foot with some pain, and was ordered a saline cathartic. Next day, in conversing with a friend, he suddenly became unconscious and fell to the ground. Recovery of consciousness and strength took place in ten minutes, with ordinary restoratives. Then the pulse was found to be heavy, full, and twenty-four beats to the minute. The recovery of sight, speech, hearing, and intelligence was perfect; the skin sensibility, normal. No loss of sensation anywhere, no impairment of power, no dulling of the sensorium, were to be detected. In short, the nervous symptoms were *nil*. Nor did gastric symptoms develop. No vomiting, pain, flatulence, were at all present; at least at first. And in the next following days, with the pulse remaining as at first, the general improvement was so marked that the patient demanded to be let up to attend to his business, and to be fed as usual, which, however, was denied him.

At this period it became desirable to determine what had caused this slowing of the pulse, which varied from twenty-four to thirty, but usually held twenty-eight beats per minute.

A slow pulse, even quite slow, has been found in sharp attacks of jaundice, when the blood was acutely vitiated by admixture with the foreign excretion. It has been found as a result of pressure on the brain, no matter from what cause—displaced bone or effused blood. A slow pulse is also thought to be the likely result of an abnormal excitation of the pneumogastric nerve, the inhibitory nerve of the heart, the nerve which regulates, slows, and governs its movements. When the nerve is cut the heart-beats increase rapidly, beyond counting, and, in fact, the organ works without control. When the nerve is unduly irritated the hold-back force is increased, and the heart slows up in the same measure. When the pneumogastric is subjected to a faradic current the heart will stop altogether. I may remark here that this quality of the pneumogastric is by some physiologists attributed to the nerve-fibres it receives from the spinal accessary, and that a detachment of the latter nerve from its origin near the medulla oblongata seems to have the same effect as a cutting of the pneumogastric. On the other hand, the branches of the sympathetic, with their ganglia, are regarded as the main acceleratory nerves, and a degeneration of those might have an effect similar to an irritation of the par vagum, the inhibitory nerve.

Finally, a very slow pulse may result from states of great debility—though it is more likely to be very fast and small—or it may result from weakness of the heart-walls and inability to respond readily to the impression of the entering blood. This weakness may be a simple dilatation with thinning of the muscular walls, or it may be a fibrous or a fatty degeneration of these walls, or it may be a thinning and anæmia of the walls without dilatation or degeneration.

In the consideration of these points in reference to my patient I was able at once to exclude icterus; next, to close out any brain-pressure; for the perfect normality of the mental power and of the reflex actions, of the functions of mobility and of sensation, showed that there was no pathological condition of the nervous centres. A pressure upon, or an excitation of, the pneumogastric nerve was, after some reflection, declared against on the basis that 18 to 20 regular respirations per minute, and no gas-

tric or laryngeal disturbances cleared of suspicion that nerve which supplies lungs, stomach, liver, and larynx equally with the heart. Being thus especially referred to the latter organ, the heart, a very careful examination was made. The results demonstrated no notable extension of area, that is to say, nearly normal proportions: No displacement; a slight mitral murmur covering the beginning of the systole, and best heard over the left auricle; a faint and muffled beat, and no perpetuation of the murmur into the aorta.

The diagnostic deductions derived from this were: No dilatation and no enlargement of the organ; no pericardiac effusion; no valvular disease—for the slight murmur was attributed to another cause—and a thinned and degenerated condition of the walls of the heart. When the muscle of this organ undergoes a degenerative process of a fatty nature, it is either in sympathy with a general adiposity of the system or in consequence of interference with its special nutrition. In this case there was no pronounced fattiness, although the patient was in good flesh, and it was left to the judgment to attribute the disturbance to an embolus or to an atheromatous condition of the arteries supplying the heart. If there had been a great development of fat in the system generally, that condition known as fatty infiltration, and which consists of a ponderous deposit of fat around the heart, and interpenetration of fat between the bundles of muscular fibre, might have been credited with weighing down and impeding the organ. If there had been a weak pulse, unsteady or irregular, the diagnosis of degeneration of the muscle-fibre into adipose tissue would have been warranted. But, with a muffled impulse, there was a full, massive pulse—yet a very slow pulse. Under these circumstances I found it impossible to determine the exact status of the case, and only hazarded the following theory: An embolus stopping one of the coronary arteries, or an atheromatous condition impairing both coronary arteries, may so have diminished the nutrition of the organ that the walls have begun to atrophy. But beyond this, that the ganglia of the sympathetic plexus which supply the heart are dulled in sensitiveness and react but slowly to the stimulus of the entering blood. Thus a large beat, but an infrequent one, could be caused, and this condition corresponds to that of my patient. As the muscle thins or deteriorates I should expect the beat to lose its force.

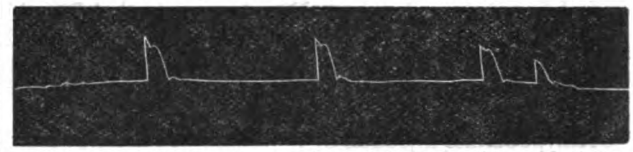
As for the patient, he had many previous conditions to make a fatty heart probable. He was not a very active man, a hearty eater, a constant, but moderate, consumer of spirits, and had had some slight rheumatic attacks long ago. It is about four years since he applied for insurance, and was remanded for repeated examinations on account of a pulse between 90 and 100. He consulted me, and I advised to stop smoking—he being an inveterate smoker. He did so, and on re-presentation was found admissible. His heart was examined then, and no exception taken to it; so it was likely in fair condition and in good working order.

The idea of an embolus of the coronary artery is, then, not only evolved from his present condition but from the suddenness of its occurrence. There is no evidence that his heart beat out of the usual rhythm up to the time of the seizure I have described.

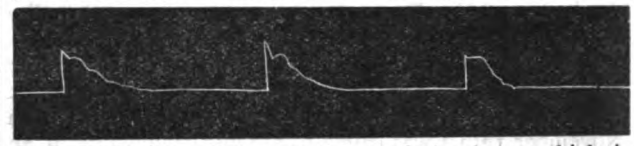
The course of the difficulty is interesting. Three months after this primary attack the beats had ranged up to 30, but subsided gradually to 22, 20, and, at times, to 18. At first the most trifling exertion caused cyanosis of the face and a convulsive rigidity of the muscles—in fact, an appearance of strangulation. The ordinary strain of urination, and the least effort in voiding fæces, brought on this state. In an instance of dietetic imprudence, attended with eructations, the symptoms became alarming. And on the surreptitious employment of a laxative, attended by four or five movements of the bowels, they held out for such lengths that death was expected during their continuance. The face became blue, the eyes protruded, the respiration was gasping, with labored puffing forth of the cheeks at each breath, the muscles were rigid, and—it was subsequently claimed—sight and hearing were lost. The pulse—well, the pulse leaped up to 120 to 130 in the minute—became very small and almost imperceptible. With the rally of forces the pulse relapsed into full beats of 24.

In the main this patient was without inconvenience, and his system seemed to accommodate itself to the new condition. He urinated and defecated without disturbance, ate even heartily, smoked, read, sat up for hours, took little walks, and sustained animated conversations. From a state of utter quiet and recumbency he gradually and very gently was emancipated to this status, and seemed to bear unconcernedly what at first seriously threatened his life. But the rate of pulse-beats indubitably grew less.

The literature on this subject is exceedingly meagre which must be my excuse for this full account. I add



sphygmographic tracings, taken with the assistance of Dr. Arthur J. Wolff, of this city, who kindly photographed them, and who was my consultant in the case. The time of taking each was seven seconds. They represent the pulse at 18 beats and at 22. Occasionally there came a



fainter but immediate repetition of the beat, which is shown in two tracings.

Let me attempt an explanation of the pulse-rise during the convulsions. To begin with, the heart beats slower and slower; less oxygen is admitted to the blood; the

tissues become saturated with carbonic acid—in other words, the patient becomes asphyxiated. This makes itself felt first in the brain. As a consequence, the nerves of special sense become inert first; next, the adjoining nerves. Presently the pneumogastric loses its power, and with it, its grip on the heart. In a moment the pulse leaps up, we have 120 to 130 beats per minute, and oxidization is restored. The pulse regains its former quality.

Death ensued in the fifth month, after a few convulsive attacks, and in one of them. All were attended by appearances of cyanosis and suffocation. The intervals were clear, and not burdened with discomfort.

The autopsy, made twelve days after death, demonstrated a heart weighing seventeen and one-quarter ounces. The orifices of the coronary arteries were dilated, the arteries themselves patent, the coats normal. The aortic valves held water. The mitral orifice admitted three fingers; the tricuspid, four fingers. The muscular tissue was red and of firm consistence; the outer coat, of brownish tinge. The ventricles were dilated, the right especially; the walls of both hypertrophied. Microscopic examination of the muscular tissue demonstrated fatty degeneration.

---

A Case of Spontaneous Cow-pox has been discovered in the herd of a gentleman living in Newton, N. J. We are informed that this is the third case of original cow-pox that has appeared in the United States. We adopt the expression "spontaneous" cow-pox, without admitting that this or other specific disease arises *de novo*.

## REMARKABLE HEMORRHAGE IN TYPHOID FEVER.

By O. H. MERRILL, M.D.,
CORINNA, ME.

F. B—— was taken sick with typhoid fever September 15, 1884. The temperature was noted to be 105° F. in the evening, unless quinine had been administered in antipyretic doses. There was no diarrhœa, and very little abdominal tenderness. In fact the bowel symptoms were "conspicuous by their absence." The case ran along in a common sort of way till September 23d. At that time, without any warning whatever, there was a perfectly overwhelming discharge of blood per rectum. Three large evacuations occurred before I could reach him. On my visit I found the pulse so rapid and so weak that I could not count it. The temperature was 96° F. He could barely whisper, and by that means indicated that he felt like having another evacuation, but he did not have any more.

A hypodermic injection of morphine was administered, and two fluid drachms of the fluid extract of ergot were also injected into his arms and legs. Ice was applied to the abdomen, and absolute rest enjoined. The first evacuation which was normal occurred ten days later. It was five days after the hemorrhage, before the temperature reached 104° F. From that point the case ran an ordinary course, and on October 21st the patient was discharged. Nothing further was seen of him till November 5th, some two weeks afterward. He then had an attack of bronchitis, in which the temperature was 101° F. On November 12th I was called to see him on account of an alarming epistaxis. Syringing with strong astringent solutions, applications of ice, and plugging the anterior nares were tried one after another, with no good result; the blood simply passing backward, and being either swallowed or spit up. Finally, as the patient was now in extreme danger, the nostrils were cleared of coagula, and the posterior nares very firmly plugged. Then a tampon was inserted into the anterior nares, and it was supposed that the case was under control. Nevertheless, in a short time, blood began to drop from one eye at the rate of thirty drops per minute. Nothing further was done except to give large doses of ergot, and the bleeding from the eye became less and finally stopped. The plugs were removed on the third day, and no further hemorrhage took place. During the epistaxis it was noted that the urine was heavily loaded with blood. Blood was also vomited at this time, but it was supposed that it had been swallowed.

The patient, then, to recapitulate, discharged blood from rectum, nose, penis, eyes, and mouth in very large quantities—so large indeed that on two different occasions he was believed to be in extreme danger. Nevertheless he recovered perfectly, but ever afterward evinced a deeply religious tendency, and is even now engaged in preaching the gospel with more or less success.

## HIGH TEMPERATURE IN TYPHOID FEVER.

By JOSEPH N. STUDY, M.D.,
CAMBRIDGE CITY, IND.

In looking over a number of text-books as to what is said regarding high temperature in typhoid fever, I find that there is a unity of opinion that the prognosis in this disease is exceedingly grave in proportion to the height which the temperature reaches for any prolonged period of time.

This opinion is abundantly supported by the statistics of our best-regulated hospitals.

That the prognosis in this affection cannot always be judged by the height of the temperature, I believe medical men frequently have opportunity to observe. That many persons die from this disease with a very moderate increase of temperature, is a well-known fact, and it cannot be denied that there are individuals who possess an idiosyncrasy to resist high temperature and diseases.

In giving an opinion as to a probable prognosis in typhoid fever, these facts should not be entirely overlooked.

Within the past few years I have had the opportunity of treating a few such cases where the temperature reached an alarmingly high point, and continued high for a prolonged period of time. And at the same time my patients presented no alarming symptoms further than the high temperature, and made a good recovery.

Permit me to relate two such cases.

I attended the family of Mr. X——, American, in July. The family consists of Mr. X—— and wife; daughter, aged nineteen; son, aged twelve; infant, aged eight weeks, and Mr. D——, aged seventy-two.

All became affected excepting Mr. D——. In the cases of Mr. X—— and son the fever pursued an ordinary course, convalescence being established after the usual length of time.

In the cases of Mrs. X—— and daughter the fever pursued an unusual long course before convalescence was established. The temperature of these two was taken daily between four and six o'clock in the afternoon. Mrs. X——'s temperature for twenty-six days registered from 103⅔° to 105⅓° F., average 104¼° F. The daughter's temperature for thirty-two consecutive days registered from 103½° to 106⅘° F. in the axilla, the average afternoon temperature being 104⅘° F. On one day only was her temperature taken in the forenoon, and it then registered 105° F. in the axilla. Both patients became greatly emaciated.

The mother nursed her infant for some days, until her milk failed. The child during this time lost flesh and was exceedingly fretful; its temperature was occasionally taken, and showed an increase of from one to three degrees.

The mother took little medicine, indulged in the most imprudent diet, and remained up and about the room all the time. The daughter remained in bed forty days, partaking freely of milk and liquid food.

Antifebrin was given a few times to the daughter, and would promptly reduce the fever about three degrees, but the depression was so great it was discontinued. The source of infection was an open well, which contained a large quantity of stinking mud, rusted tin cans, and other refuse matter. For accuracy, four different thermometers were compared in recording the temperature.

---

A Chinese Paretic.—Dr. Matthew D. Field, of this city, writes: "Chow Hays, a native of China, aged forty-two, married (?), and by occupation "washee washee," was committed by a police magistrate for examination as to his sanity. He presented well-marked physical and mental symptoms of general paresis of the insane. His case was quite typical, with grandiose ideas; was about to establish a thousand laundries, and wanted ten thousand wives. Insane Chinamen are no novelty at the pavilion for the insane, but I believe this is the first case of general paresis in a celestial in New York City. Dr. W. H. Mays, late superintendent of the Insane Asylum of the State of California, at Stockton, in his biennial report for 1885 and six writes: "There are seventy Chinese under our care, sixty-seven males and three females. In the Napa Asylum about as many more may be found. In proportion to the number of Chinese in the State, I consider mental disease particularly rife among them. In China, insanity partakes somewhat of the nature of a penal offence. Hence travellers in that country, seeing little of it, proclaim its non-existence, and base thereon deductions unfavorable to our civilization. But in Japan, where enlightened and progressive views are making rapid headway, institutions for the care of the insane are beginning to dot the land."

## EPIDEMIC INFLUENZA.

THE epidemic of influenza which we have already referred to as occurring in Russia has spread into Finland and Eastern Prussia, and is not unlikely to spread throughout Europe, and even reach this country. The disease travels rapidly, and has been known to make all Europe sneeze within six weeks, so that we may expect an arrival here before our winter months are over. It used to be thought that this epidemic moved in definite cycles of one hundred years. Although such an idea has been long abandoned, it is a curious fact that the influenza prevailed in America one hundred years ago, and Dr. John Warren, in a letter to Dr. Lettsom, says that "our beloved President Washington is but now recovering from a severe and dangerous attack of it."

In 1830 an epidemic started in China, it reached Russia in January, 1831, and by May it had spread to Western Europe; but it only reached this country in January, 1832, and then prevailed but slightly.

Another and severer epidemic started in Russia in December, 1836; within a month it appeared in London, and rapidly spread over Europe. This time, again, America was not affected. An epidemic of considerable extent prevailed in the United States about ten years ago, and there have been various mild manifestations of the disease. On the whole, however, North America does not seem to be very favorable to the development of epidemic influenza in its worst forms, and it is unlikely that we shall have a severe visitation, if we have any at all.

The disease is not dangerous, except sometimes to children or the aged, while the former often show a decided exemption.

There is no doubt that this new epidemic will prove a boon to bacteriology, for Seifert's micrococcus has not quite satisfied pathologists, and we anxiously await the announcement of the discovery of the influenza bacillus, only regretting for the sake of American science that the miasm always begins in the East and travels West. The bacteriological laboratories of Europe will therefore have the first chance.

The disease is undoubtedly due to some micro-organism which floats in the air, and which infects the human system, but is generally killed in so doing. For influenza is but slightly if at all contagious.

We observe that some feeling of alarm prevails lest this epidemic be a precursor to cholera, as was the case in 1831 and 1847.

There have been, however, plenty of cholera epidemics without a preceding influenza, and a great many influenza epidemics without any associate cholera. The micro-organisms of the two diseases are as essentially different as are the diseases themselves. The cholera germ lives in water and soil, the influenza germ in the air. The relation between the two diseases has been, we believe, purely accidental.

## COMPULSORY NOTIFICATION OF INFECTIOUS DISEASE.

IT is time that the medical profession take some decided stand with regard to the subject of compulsory notification of infectious diseases. At present we are sued by the patient if we send a notice, and sued by the Board of Health if we do not.

Illustrations of both these contingencies of modern medicine have occurred in or near this city, and must be fresh in the minds of the profession. A doctor was recently imprisoned by the stupid action of the Brooklyn Board of Health because he did not send in a notification of a case of yellow fever, which was not yellow fever after all. Recently a Boston physician was fined $100 and costs for not reporting promptly a case of small-pox. The physician claimed that he did make the report as soon as he was convinced of the nature of the disease. He is known to be an intelligent and experienced man; yet, despite his protests, he was fined. The doctor is a poor man, in poor health, and with a family to support. He can ill afford to pay the sum exacted, nor should he be compelled to do so.

It is well known that chicken-pox sometimes takes a severe form and for a time closely resembles small-pox. We can recall a case in which, after a notification of possible small-pox, the City Board of Health physicians paid visits for three days before they could decide as to the nature of the disease.

A young man is now suing the city of Philadelphia for $50,000 because he was sent to a small-pox hospital when he had only the measles. He subsequently caught the small-pox in the hospital, and barely escaped with his life. The Brooklyn Board of Health is now being sued for having insisted that a case of remittent fever was one of yellow fever. Officers of hospitals for infectious diseases constantly find mistakes in diagnoses made, and sometimes make them themselves. Some illustrations of this are given in a recent issue of the *British Medical Journal.*

"Dr. R. D. R. Sweeting, in his 'Report on the Western Hospital of the Metropolitan Asylums Board for 1887,' states that 21 cases of measles (and rötheln) had been admitted during the year, 13 certified as scarlet fever and 8 as enteric fever; again, Dr. R. A. Birdwood, in his 'Report on the Small-pox Hospital Ships for 1888,' states that four patients, not suffering from small-pox, had been admitted on mistaken diagnoses; the diseases they were actually suffering from were scarlatina, syphilis, eczema, and ecthyma."

From all this it is evident that physicians should not be made responsible for not promptly notifying authorities of the nature of an infectious disease, even if they accept the duty, unconstitutionally forced upon them, of serving the State without remuneration.

### MEDICAL EXAMINING BOARDS AND "LIBERTY."

OUR correspondent, Dr. Mendelsohn, contributed a very eloquent letter to our columns last week, regarding the subject of the regulation of medicine, and of medicine in its relation to the State generally. Much that was said about the debasing influence of the spoils system upon public medical officers is, unfortunately, true.

Upon the subject of the regulation of medicine by the State, however, our correspondent betrays a profound ignorance. The purpose of this regulation is not to protect the medical profession alone, but to give to the people a reasonable assurance that a class of persons upon whom life, health, and the prevention of epidemic disease often depends, should have some educational qualifications.

The danger of the State going too far in its interference with medical affairs exists, but is very slight, and not now imminent. It is not safe or logical to infer from certain results in an absolute monarchy that similar results will occur here in a free republic. This is a country where laws are made by the people and for the people. If a law is bad it can be remedied without petitioning an imperial chancellor.

The statement that laws regulating medical education and practice have done no good, and had no part in securing our present progress, is quite erroneous, and shows much ignorance of the history of medical education in this country. We commend our correspondent to some impartial historic studies.

It is not claimed that State aid is a specific for bad educational methods or low professional standards. It is one means, however, and a decidedly helpful one in hastening on the time when higher standards will be demanded by universal public opinion.

A State Examining Board will not secure a medical millennium, but it may prevent the development of bogus and purely business medical colleges, which turn out dishonest and ignorant men, who fail, or do not seek, to pass at reputable institutions.

It is quite possible that in a few thousands of years matters medical will have naturally and spontaneously reached perfection, as some apostles of personal liberty seem to think. But it is not the part of wise men to trust entirely to such general optimistic conceptions of the universe. It is better to start things on so as to taste a little of the beatitude in our own day.

---

### IODIDE OF POTASH IN HEART DISEASE.

THE potassium salts, including the iodide, have long ago been shown to have a paralyzing effect upon the heart in large doses. M. Germain Sée now tells us, however, that in medicinal doses potassium iodide is a cardiac and vasomotor tonic. We must doubt the value or thoroughness of Sée's experimental studies, for they seem to ignore as well as contradict all previous work. But the clinical conclusions may be true enough. M. Sée asserts that the cardiac affections which are mostly benefited by this treatment are adiposis, fatty degeneration, weakened heart, cardialgia, nervous or organic irregularity of the organ (arythme), especially in the aged. As to aneurism of the aorta, iodide of potassium was the only remedy that gave real satisfaction. In all heart disorders, far from being a depressor, it was particularly useful in lesions with debility. It raises the energy of the heart and the vascular pressure. Then, in dilating later on all the arteries, the flow of blood is facilitated and the organ recovers its contractile powers.

---

## News of the Week.

THE EPIDEMIC INFLUENZA is said to have appeared already in Paris, though not in Berlin or London.

THE SOUTHERN MEDICAL RECORD has passed into the hands of Dr. D. H. Howell, of Atlanta, Ga.

DARTMOUTH MEDICAL COLLEGE held its annual commencement November 26th, and graduated twenty-one students.

COOPER MEDICAL COLLEGE OF SAN FRANCISCO held its twenty-sixth annual commencement November 21, 1889, and graduated a class of 41, out of 64 matriculates.

A HOSPITAL FOR INCURABLES IN PITTSBURG.—The sum of $800,000 has been bequeathed by the will of the late Mr. J. H. Schoenberger, to found a hospital for incurables at Pittsburg, Pa.

DR. JOHN S. BILLINGS has, with the approval of the Secretary of War and of the Surgeon-General, accepted the position of Medical Director of the University Hospital in Philadelphia, to which he was recently elected.

DR. HANS VIRCHOW, Privatdocent in the University of Berlin, and Prosector in the Anatomical Institute, has been raised to the rank of Professor Extraordinarius. Dr. Hans Virchow is a son of the celebrated pathologist.

DR. BRAMANN, first assistant in Professor von Bergmann's clinic at Berlin, who performed tracheotomy on the late Emperor Frederick the Third, has declined to accept a "call" to Greifswald as Extraordinary Professor of Surgery.

QUACKERY IN BRAZIL.—On October 19th the late Brazilian Minister of Justice sent a circular to all presidents of provinces, directing them to institute criminal proceedings (*proceder criminalmente*) against all persons practising medicine without legal title. It is to be hoped that in this point the new Republic will show itself as enlightened as the Imperial Government which it has supplanted.

WEIGHT AND FEEDING.—Drs. A. V. Meigs and J. A. Scott wish us to believe that if a person weighs just 100 lbs. and then takes into his stomach just one pound, he will not weigh 101 lbs., but only 100.8 or 100.9 lbs. In other words, weighing just before and just after eating will not give exactly the amount eaten. These observations of our Philadelphia contemporaries throw a dark and depressing shadow upon the historic researches of the great Sanctorius, who passed his life in eating, excreting, and weighing. But perhaps Philadelphia scales are wrong.

AT THE OPHTHALMOLOGICAL CONGRESS recently held at Heidelberg, the Graefe prize was awarded to Professor Deutschmann, of Hamburg, for his essay on "Ophthalmia Migratoria." Dr. Uhthoff, Privatdocent in the University of Berlin, received an honorable mention for his work on the "Influence of Chronic Alcoholism on the Visual Organs of Man."

A NEW GYNECOLOGICAL OPERATION, termed Salpingostomy, has been devised by Dr. Skutsch. Its object is to save the tubes instead of removing them when they are diseased. In the patient on whom the operation was done, there was obstruction and dilatation of tubes. A Pravaz syringe was employed in order to puncture each tube and ascertain its contents. As clear yellow serum was drawn away, the operator determined to save the tubes. An oval piece, about one square centimetre in size, was cut out of the outer end of each tube, and the mucous and serous coats united by fine silk sutures around the border of the hole thus formed. A sound was then easily passed from the tube into the uterine cavity on both sides. The patient made a good recovery, and was relieved of her pains, but a long after-history is not given. In some cases of pyosalpinx it would be advisable, he thinks, to sew the ends of the tubes to the abdominal wound, to open them, and allow them to discharge pus externally. When the discharge ceased to be purulent the tubes might be freed from their artificial attachments and replaced in the pelvis.—*British Medical Journal.*

A MEDICAL ASSOCIATION OF IRREGULARS has been organized in Massachusetts, under the name of the Massachusetts Constitutional Liberty League. It recently met, and after a series of lurid "*whereases*,"

*Resolved*, That all organized so-called irregulars be and are hereby invited to co-operate with the Massachusetts Constitutional Liberty League and the National Constitutional Liberty League, in resisting restrictive legislation, or any legislation suggested and supported by regulars.

*Resolved*, That all unorganized so-called irregulars be especially and earnestly urged to immediately identify themselves with the State and National League.

*Resolved*, That all patrons of so-called irregular practice owe it to those who have served and saved them, especially after the regulars had utterly failed to cure or even benefit them, to sustain them in their struggle for constitutional liberty with their sympathy and substance.

THE NEXT PHARMACOPŒIA.—Attention is being called to the fact that the next revision of the Pharmacopœia will be one of the most important in the history of the work. Medical societies are asked to bear this fact in mind.

DISPOSITION OF STABLE REFUSE.—At a meeting of the Section on Public Medicine of the New York Academy of Medicine, Dr. Jos. D. Bryant said that there are sixty thousand horses in the city below One hundred and Thirty-fifth Street, and the refuse amounted to about nine hundred thousand pounds daily. About three hundred thousand dollars is invested in the business of removing this refuse. He urged that there would be great benefit to the public in compelling all this refuse to be baled before it is carried through the streets. Commissioners Bryant and Smith had agreed on a report recommending that after May 1, 1890, baling be made compulsory. The meeting voted its approval of the report.

ASSOCIATION OF LIFE INSURANCE MEDICAL DIRECTORS.—About twenty-five medical directors of various life insurance companies of this country met in this city last week, and organized the "Association of Life Insurance Medical Directors of America," with the following officers: *President*—Dr. J. M. Keating, of the Pennsylvania Mutual; *Vice-Presidents*—Dr. G. W. Russell, of the Ætna, and Dr. Lewis McKnight, of the Northwestern Mutual; *Secretary*—Dr. Frank Wells, of the John Hancock; *Treasurer*—Dr. J. W. Brannan, of the Washington; *Executive Committee*—Dr. J. M. Keating, of the Pennsylvania Mutual, Dr. Frank Wells, Dr. J. W. Brannan, Dr. Henry Tuck, Dr. G. S. Winston, Dr. E. W. Lambert, and Dr. Edgar Holden. The object of the Association is "the promotion of medical science as applied to life insurance by the personal intercourse of the members, presentation of papers, discussions, and such other methods as may be found desirable; and also the encouragement of social and personal relations between its members, and the advancement of the general interests of life insurance." The next meeting of the Association will be held in May, 1890, and it will meet annually thereafter during the same month.

ROBERT GARRETT'S MEDICAL BILL.—The suit of Dr. Nathan R. Gorter against Robert Garrett, for $25,000 for professional service, has been settled. Dr. Gorter offered to compromise for $18,000; the proposition was accepted and the money paid.

HORSE-MEAT SAUSAGES.—Some alarm has been created by the discovery that a Long Island establishment has been making sausages out of horse-meat. There is, however, nothing poisonous or unnutritious in horse-meat. The only objection that can be made to this kind of food is that sound and healthy horses are too expensive to be eaten, hence it is to be assumed that the horse-meat of butchers' shops does not represent the noblest type of a noble animal.

THE ISABELLA HEIMATH RETREAT, TENTH AVENUE AND 190TH STREET, NEW YORK.—There are two convalescent wards at the Isabella Heimath, each containing fourteen beds. They are intended for convalescents who have no home in which they could find rest and care. The trustees are ready to admit, for a term not exceeding four weeks, convalescents of both sexes needing care and rest after acute internal diseases or surgical operations; and no distinction shall be made on account of creed or nationality. Applications, bearing the indorsement or recommendation of the attending physicians or surgeons, should be addressed to August Caillé, M.D., 185 Second Avenue; A. G. Gerster, M.D., 56 East Twenty-fifth Street; A. Jacobi, M.D., 110 West Thirty-fourth Street; H. G. Klotz, M.D., 222 East Nineteenth Street, consulting physicians.

TOBACCO HYSTERIA.—At a recent meeting of the Paris Hospital Medical Society, M. Gilbert showed the members a patient, aged sixty-two, who had worked in a tobacco factory forty years, and smoked excessively. About a year ago he exhibited symptoms of motor and sensory disturbance in the lower limbs. These were apparently cured by the influence of a magnet, but soon afterward reappeared in the form of motor hemiplegia, with sensory anæsthesia. These cases often occur in tobacco factories. MM. Gilbert and Letulle diagnosed the case as toxic hysteria. M. Hayem objected to the constant misapplication of the term hysteria.—*British Medical Journal.*

"TOXIC" NOT "TONIC."—On page 606 of THE MEDICAL RECORD, in the notice of "Nothnagel on Heart Disease," in the second line of second paragraph, *tonic* should have been printed *toxic* effect.

Society of the Alumni of Charity Hospital.—The following officers have been elected for the ensuing year: *President*—Dr. D. Bryson Delavan; *Vice President*—Dr. Ramon Guitéras; *Secretary*—Dr. W. L. Baner; *Treasurer*—Dr. A. T. Muzzy.

The late Dr. George Williamson, who died in this city on December 8th, was well known to the younger members of the medical profession as an earnest worker and a true Christian physician. He graduated from the University of New York in 1875, and served as interne in the Epileptic Hospital and Orthopœdic Hospital. For many years he was one of the assistants at the Manhattan Eye and Ear Hospital. He leaves a widow but no children.

A Chicago Hospital Criticised.—The Cook County Hospital, says *The Medical Standard*, has for years, with some honorable exceptions, been a collection of servile tools of the vilest political ringsters. In place of upholding the dignity of the profession, the County Hospital staff has made the name of hospital physician a by-word and a reproach. The performances of several of the members of the Board of 1888 were so unprofessional as to merit the censure of the Chicago Medical Society.

A New Method of Antirabic Inoculation.—Inspired by the belief of M. Pasteur, that the desiccation of spinal cords obtained from animals having died of rabies diminishes the quantity and not the virulence of the rabic poison, M. Hœgyes, of Buda-Pesth, was led to try the effect of simple dilution, and he has successfully carried out seventy vaccinations on this plan without the production of any untoward symptoms. He soaks one part of diseased cord in a sterilized solution of sea salt (7 grammes to the litre), the proportion varying from 1 in 10 to 1 in 10,000.—*Medical Press.*

A Nursing Heroine.—The spirit of Florence Nightingale lives in the person of Sister Thérèse, Superior of the Sisters of Charity now serving in Tonquin, who has recently been decorated by the General in command. When she was barely twenty-five she was wounded at Balaclava. At Magenta she again received a wound. She accompanied French soldiers to Syria, China, and Mexico. In the Franco-German war she was grievously wounded at Reichshofen while attending the cuirassiers who fell in that memorable charge. At a later stage of the same campaign she distinguished herself by seizing a bomb which fell into an ambulance, and carrying it away eighty yards, when it burst, seriously injuring her alone. She was scarcely recovered from the effects of this injury when she volunteered for service in Tonquin.—*British Medical Journal.*

A New Test for Albumin in the Urine.—Trichloracetic acid is stated by M. Boymand in the *Répertoire de Pharmacie* for the present month to be the best reagent for the detection of albumin in urine. It is more reliable and possesses none of the disadvantages of the ordinary tests, such as nitric acid and metaphosphoric acid. It has also the power of precipitating that peculiar form of albumin which is thrown down by heat but redissolved on the addition of acetic acid. Trichloracetic acid is obtained by the action of chlorine gas upon acetic acid, three atoms of the hydrogen of the radical acetyl being replaced by chlorine. The compound is represented by the formula $CCl_3CO.OH$. It is a crystalline solid body, very soluble in water, and it forms salts analogous to the acetates. Acetic acid may be regenerated from it by the action of nascent hydrogen. The test may be used in a solid form or in solution. If the solid be employed, a small fragment is placed in a test-tube containing the urine; it sinks to the bottom and is dissolved, producing a cloudiness, or, with very clear liquids, a zone of cloud. The solution can be used either saturated or fairly concentrated. When poured upon the urine to be examined it forms a characteristic ring, like that obtained by means of nitric acid, but without producing any coloration. When the urine is rich in urate of soda it is better to dilute with distilled water, and thus avoid a cause of error which is common to all reagents. We have not been able to obtain a specimen of trichloracetic acid for the purpose of verifying the statements made respecting it as a precipitant of albumin in urine under all conditions, but we hope to do so in a short time, and to report the result of our experiments.—*British Medical Journal.*

Hypohæmatosis.—Dr. Maurel has read a paper before the Paris Academy of Medicine, on "Hypohæmatosis," which may be summarized as follows: The height, weight, and measurement of the thoracic region have a definite proportion one to the other. This proportion is variable according to age, but is definite for any given age. When what may be called the normal proportion does not exist, a series of abnormal conditions exist which M. Maurel classes under the name of hypohæmatosis. Sometimes these several conditions collectively produce a special condition—anæmia resulting from imperfect oxidation of the tissue, or, in other words, non combustion owing to imperfect thoracic development. Gymnastic exercises frequently remedy this evil, and thus act as an antidote to hypohæmatosis.—*British Medical Journal.*

As the World Gets It.—Under the title "Seven M.D.'s Beautifully Trapped," a sheet called *The Microcosm* says: "This interesting feat was adroitly accomplished in last Sunday's New York *World*, by the intrepid lady reporter and detective employed on that paper. She played sick and visited the seven prominent doctors, probably with a made-up sallow complexion, and thus obtained from each a critical diagnosis of her case. Now comes the funny, and at the same time serious, part of this exposure. Each of the seven learned physicians solemnly attributed to her a different ailment, and then each as gravely prescribed a different class of medicines. A more humiliating exposure of the humbug and empiricism of this professional business of dealing out poisons to the sick at $5 for two dozen words of Latin quail-tracks on a slip of paper, has never before been placed on record. If that single exposure does not lose the doctors of New York, in prescription receipts alone, a cool million dollars, then we sadly miss our guess." Upon all this our esteemed and valiant contemporary *The Texas Health Journal* makes serious comment and reply. First, the editor of *The Microcosm* is shown up as a "notorious and nefarious humbug," and then it is added: "We have not seen the article referred to in the New York *World*, but do not for once doubt the hysterical article written by Miss Bly, who doubtless consulted a lot of quacks and blatherskite advertisers, such as Hall of *The Microcosm*."

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, November 7, 1889.*

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

THE PRESIDENT appointed Dr. M. Allen Starr editor of the volume of "Transactions."

DR. SIMON BARUCH read a paper entitled

### A PLEA FOR THE PRACTICAL UTILIZATION OF HYDROTHERAPY.

The fact that water in the treatment of disease had been chiefly employed by empirics seemed to have prevented in some degree general recognition of its virtues by the medical profession. The author justified his appeal for its more general utilization by physiological laws and clinical results, both ancient and modern. The literature showing the value of hydro-therapeutics was very extensive, yet modern text-books dismissed the subject with a few words. There were at present but three cities in which it was much used in the general hospitals. Vienna taking the lead. In spite of professional and lay prejudice, the remedy had stood the test of time better than any other. A review of the experience of those whose names had become prominently associated with hydrotherapy was given, and brief quotations were made from such modern therapeutists as Niemeyer, Dujardin-Beaumetz, Hoffman, etc., testifying to the value of the method.

But proof of its value did not rest alone on clinical experience; it was fully supported by ascertained physiological laws. What other agent than water could produce such a variety of results, according to its mode of application? Its stimulating or depressing effects could be made to manifest themselves either directly upon the skin where applied, or upon internal or remote organs, through reflex influence. One example of reflex influence was seen in the response of the blood-vessels of the pia mater to a stream applied to the surface; if the stream were cold, they become dilated; if warm, they become contracted. The hand immersed in cold water increased in size, showing that by the use of water the blood could be driven from one part of the body to another. Water applied to the feet exerted an influence upon the cranial circulation; applied to the back, it influenced the circulation in mucous surfaces, etc. The heart also responded to temperature impressions upon the periphery. A low temperature briefly applied accelerated the heart's action; prolongation of it diminished the action. Evanescent application of a high temperature to the skin caused a decrease of the pulse-rate, quickly followed by an increase. By cooling the blood in fevers, the heart's action could be slowed, and an invigorating effect thus brought about. Having stated that the vascular tension could be modified by hydropathic procedures, he said that this influence upon the circulation was so decided, indeed, that hydrotherapy became in reality a hydraulic problem. It was a most perfect means of influencing the vascular system. He said it was to be remembered also, in discussing the value of hydrotherapy, that the vital process by which the system sought to protect itself against thermic changes had also been ascertained. Vascular spasm protected the internal organs against too rapid cooling of the surface, while the secondary effect was reaction and vigorous dilatation of the cutaneous vessels. It had been shown that by hydropathic treatment the blood-cells could be increased in number, and also improved in quality. This, and the influence upon the nervous system, produced a healthy change in the functions of nutrition, secretion, and excretion. In this country, Dr. Putnam-Jacobi was one quoted as having added to our knowledge of the physiological and therapeutic action of water.

In discussing the clinical aspect of the subject, he said he agreed with Dr. F. A. Hoffman in the statement that he did not deal with the disease, but with the sick man. He approved of Hoffman's classification of the treatment as direct (removing the cause) and indirect, but he would add a third method, that by which he could so impress the various functions of the body, chiefly innervation, as to enhance the resisting powers of the patient, and thus enable him to pass over danger-points. He claimed for hydrotherapy only the position of being a valuable but indispensable auxiliary to other treatment. By hydrotherapy he meant water at any temperature, in any form, used internally or externally in the treatment of disease. Of the three therapeutic methods mentioned, the removal of the cause of the disease directly was not always practical because of our ignorance of the etiology. In the case of gastric and intestinal diseases, we seemed to be on the threshold of discovering the cause through bacteriology. In the removal of this and restoring gastric function, water had been used with great success. Intestinal irrigation, by means of the fountain syringe and Nélaton catheter, was the most efficient method of treating several types of summer diarrhœa. The value of sipping hot water in gastric troubles had been demonstrated. Other cases in which he had found the method of marked benefit were those of neurasthenia and other nervous diseases, rheumatism, gout, scrofula, etc. The neurasthenic cases were treated differently according to whether they were of an erethitic or an asthenic nature. Two cases were cited to show that much depended in the treatment upon the temperature of the water, and the uniformity and frequency of its repetition. He said that hysteria was among the affections which would almost certainly yield to the water treatment when aided by other measures. They had discharged three cases from the Montefiore Home as cured, notwithstanding they had been sent there as incurables. No patients of any kind were admitted to this institution, except those who had been considered incurable; yet by hydropathic measures they had sent out a number as cured, who had had gout, rheumatism, sciatica, hysteria, etc. Chorea often yielded to this treatment; the active impact of very cold water by the douche was necessary here. Many cases of neuralgia were connected with anæmia and chlorosis, and were cured by hydropathic treatment; indeed, he said that if there was any condition in which the tonic effects of hydropathy were pronounced, it was functional anæmia. During the winter it was often sufficient for the patient to stand with the feet in warm water, and splash cold water on the body, the duration being only until the entire body had been wet. The result of hydropathy in the treatment of phthisis had been also satisfactory at the Montefiore Home, and one pronounced case of the morphine habit was cured. Statistics had demonstrated that the mortality of typhoid fever could be reduced from twenty-five per cent. to two per cent. by this treatment. The fact should not be overlooked that the object was not to reduce the temperature, but to refresh the nervous system, that the body might be enabled to withstand the disease. The bath should be adapted to each particular case.

DR. GEORGE L. PEABODY, having been asked to open the discussion, said he would speak only of the application of water to the treatment of a form of acute disease which was of common occurrence here, and in the treatment of which our results had been almost uniformly discreditable to medical practice. He referred to typhoid fever. It was a matter of surprise that in this city, where physicians sought to introduce into their practice all that was good and new from all parts of the world, it was necessary for one to urge the desirability of trying this procedure. He thought that the sooner we rid our minds of the fallacy that it was likely to do patients with a high temperature harm to expose them to a considerably lower temperature, the sooner would we get at the rational treatment of this grave malady. It was almost impossible to give a patient cold who had a temperature much above the normal; it was not likely that a patient with a tem-

perature of 104° F. would take cold, even if he kicked the bedclothes off and lay entirely exposed. He thought the mortality from typhoid fever in our hospitals was quite unjustifiable; it ranged anywhere from twenty-five to thirty per cent., and, here and there, it rose to fifty per cent. In the German army, where this treatment had been carried out in a large number of cases, the mortality had been reduced to below four per cent. Perhaps one reason why it had not been applied, except in a few instances, in our hospitals, was that it required two attendants and a portable bath-tub.

Regarding the method of applying it, he thought there could be no question but what the full bath, of a temperature of between 65° and 80° F., was best; the patient should be put into the bath at as frequent intervals as the temperature indicated. The temperature should be kept at or below 102° F., throughout the entire course of the disease. How much more rational was this treatment than that which he had often observed, of administering antipyretic drugs, bringing the temperature down from 105° or 106° F., to normal or below, allowing it to rise again equally high, and again bringing it down with the drug. A good many patients were brought to the hospital in a very unfavorable state, and in that case, instead of plunging them into a cold bath, he would apply the wet pack. Personally, he did not like the graduated bath; it was far more troublesome, and was less comfortable to the patient. Cold affusions on the Kibbee cot produced rather too much shock. He thought it was folly to apply cold to the surface of the body when it was already cool. We often found profound depression in typhoid fever in which the surface was cool, and the internal temperature high. It was certain that no routine habit of applying cold to the surface would apply in these cases. He could conceive of no other direct object in applying cold than to increase surface radiation, and if the heart was too feeble and could not be stimulated to pump the blood to the surface, there was no reason in cooling the surface further.

Dr. A. A. Smith hardly knew where to begin to discuss so extensive a subject. In Bellevue Hospital he had continued the treatment of four cases of typhoid fever, begun during the service of Dr. Flint, and all recovered; since then he had had five cases, in none of which the use of the cold bath seemed to be justified, since the temperature did not rise above 103.6° F. They all recovered without such treatment. This, he supposed, would be the experience of others. Unless the bath was used in a large number of cases, it would be difficult to draw any conclusions regarding its superiority over other methods of treatment. He was, however, a warm advocate of hydrotherapeutics. He said that if there was any class of cases which made him very unhappy, and which he failed to make very happy, it was that of the neurasthenics. If Dr. Baruch could teach us how to cure these patients by hydrotherapy, he would put us under great obligations. Regarding the cure of hysteria by this method, he must admit to some scepticism, yet he hoped others would try it and have equal success. Patients with hysteria deserved our earnest attention, for he believed that underlying almost every case there was some cause in irritation, or disturbance, which should not be ignored. He was a great believer in the wet pack, and he thought that its only benefit did not consist in reducing the temperature; he had felt that the soothing of the nervous system was as great an object to attain as the reduction of the temperature. Warm water had been of great service in reducing the temperature. He had known the temperature in scarlatina to fall a degree and a half from no other treatment than wrapping the patient in a sheet wrung out of warm water, repeated several times during the twenty-four hours. It often banished delirium and muscular disturbance, caused sleep, and reduced the temperature.

Dr. M. Putnam-Jacobi gave the details of a case of typhoid fever treated in the New York Infirmary by water-baths. She differed from Dr. Peabody in the view that the benefit was alone from the reduction of the temperature. She saw no reason for pushing it further than to produce the desired reduction of the temperature and beneficial influence on the circulation and nervous system. She did not think, therefore, that hard and fixed rules for its use in typhoid fever should be necessary.

Dr. G. B. Fowler thought the physical properties of water commended its use in the treatment of disease to all physicians, and he was rather surprised to hear that the bath was as little used as Dr. Baruch had stated. He certainly had used it ever since he began practice, in all cases of hyperpyrexia. In the angina of scarlet fever, diphtheria, etc., he kept the throat almost frozen, using ice, and certainly with very good results. He expected it to do more than reduce the temperature. Its results were less violent than those of the therapeutic measures usually employed. The author had only hinted at one method of using water, namely, by drinking. Dr. Fowler regarded this as important in the treatment of fever as the external use of water. He gave his patients an excess to drink, and in the sickness of children gave it to them in the nursing-bottle. He saw a great many cases sometimes called neurasthenia; women with constipation, loss of appetite, catarrh of the alimentary tract, etc., the blood-corpuscles on the glass sticking to one another, crumpled, the urine scanty, want of free perspiration. Here the clinical facts pointed to a deficiency of water in the system. One might as well try to raise a crop without rain as to nourish an individual properly without water.

Dr. Baruch closed the discussion.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, June 12, 1889.*

William P. Northrup, M.D., President, in the Chair.

### REPORT OF THE COMMITTEE ON MICROSCOPY.

Drs. Henry P. Loomis and Ira J. Van Gieson, the Committee on Microscopy, reported that the microscopical section referred to them at the last meeting of the Society, which was obtained from the bone presented by Dr. Lewis H. Sayre, was found to be filled with dilated and irregularly shaped medullary spaces encroaching upon the bony trabeculæ. In the semicircular depressions at the margin of the trabeculæ were seen granular-looking, multi-nucleated cells (osteoclasts). In some places these cells were almost surrounded by bone. The committee diagnosed the lesion as that of rarefying ostitis.

Dr. William P. Northrup presented specimens illustrating

### GENERAL TUBERCULOSIS — THROMBOSIS OF THE LEFT MIDDLE CEREBRAL ARTERY—CHEESY MASSES IN THE MEDULLA.

A male child aged five months was, when first seen by the house physician, lying in bed in the attitude of a boxer. The head was markedly retracted and turned to the left, the left elbow was raised to the level of the shoulder, the forearm flexed on the arm and held in a plane on a level with the elbow, the hand clinched with the thumb in the palm. The right arm was extended on the level of the shoulder and its fingers clinched over the thumb. The knees were moderately drawn up. Nothing pictures the position better than to imagine the child on its feet in the attitude of a boxer. The abdomen was distended but not tense. Sensations were normal. Respiration was of the Cheyne-Stokes character; pulse rapid and weak; temperature, 99.5°; lungs normal; tache cérébrale marked; cry not meningeal; pupils dilated but not reacting. The child died three days after the first recorded observations.

*Autopsy.*—Body emaciated. Attitude the same as described above. *Brain:* Tubercles sprinkled over whole cerebrum, thickest along the course of the vessels. About

the left middle cerebral artery, in its first inch and a half, was a mass made up of tubercle tissue and inflammatory exudation. The artery was blocked by a thrombus and the brain-tissue to which it was distributed was diffluent, while the remaining and surrounding substance was firm. The diffluent mass left an opening into the left ventricle. The ventricles seemed not to be dilated, or only moderately. In the wall of the fourth ventricle, at the junction of the medulla and pons, was a yellowish, spherical cheesy mass, about four millimetres in diameter. A similar mass, though smaller, was found lower down in the opposite wall. The spinal cord was normal. *Lungs:* Tubercles large, opaque, and abundant; cavity of capacity of 3 ss. Bronchial lymph-nodes enlarged and cheesy; no pneumonia. *Liver* enlarged, tubercles numerous. Gall-ducts thickened and tubercular. Heart normal. Mesenteric glands large and cheesy. Peyer's plaques swollen, but no ulcers.

Dr. Northrup presented a second specimen, illustrating

ABSCESS OF THE SCALP FOLLOWED BY THROMBOSIS OF THE LONGITUDINAL SINUS, AND PYÆMIC ABSCESSES IN THE BRAIN AND LUNGS IN AN INFANT.

The patient was a male child, two months and six days of age, who was brought to notice with an abscess of the scalp, over the vertex; no history of injury. Three days later, and two weeks before death, he became restless, fontanelles depressed, temperature gradually increasing to 103° F., with twitching of the left arm and jaw, and rolling of the head. He gradually failed, developing in the last days of life an ulcer on the tip of the tongue; fine râles over both chests, and became pale, stupid, and aphonic.

*Autopsy.*—Extremely emaciated; abscess over vertex nearly healed; beneath the site of the abscess the bone was reddened; the longitudinal sinus contained a firm old clot two and a half inches long, having its middle just below the centre of the abscess. Slight redness of the dura mater; no exudation upon its surface. The wall of the sinus seemed normal; across its cavity stretched a fine bifurcated filament. This was located in the middle of the clot; its tissue was normal. *Brain:* The right lateral surface contained six or eight small abscesses varying in size up to a diameter of from three to four millimetres. These extended inward from the pia mater and were fusiform in shape; the contents, fluid creamy pus. There was no meningitis. Post-mortem softening was advanced. *Lungs:* Scattered broncho-pneumonia with marked infiltration of the small bronchial walls. On the surface of the right lung, just under the pleura, was a small abscess similar to those of the brain. There were no other abscesses found. The thrombus of the longitudinal sinus, the small abscesses of the brain, and the abscess of the lung showed abundant colonies of streptococci. Numerous colonies were distributed in the lungs with evident beginning of abscesses.

Dr. H. P. Loomis said that he had recently seen a case somewhat similar to the one reported by Dr. Ely. Inoculation of a rabbit with the cheesy material from the bronchial glands showed that it was tuberculous.

Dr. Northrup presented a card-specimen of

VEIN TUBERCLE,

from a case of discrete miliary tuberculosis of the lung in a child (see p. 657). The specimen was of unusual interest from the fact that a fortunate cut across one vein had passed through two tubercles growing from the inner surface of the same vessel. A second microscope slide showed the two tubercles stained for tubercle bacilli, in which the micro-organisms were distinctly demonstrated. The tubercles were of typical structure, containing granular giant-cells and tubercle bacilli.

The Society then went into executive session.

---

Creosote in Diabetes.—In doses of from four to ten drops a day creosote is said by Dr. P. Valentine to have yielded excellent results in several cases of diabetes mellitus.

## PREPARING FOR THE INEVITABLE.

To the Editor of The Medical Record.

Sir: Your able editorial on life insurance for physicians, in The Record of November 23d, abounds in good suggestions. But will it go far enough? That is, will enough physicians join a mutual benefit association to pay our widows a sum that, at five per cent. interest, would keep those we leave behind in anything like the circumstances they had been accustomed to? I think it exceedingly doubtful. Making allowances for "bad risks" that would or should be rejected, with two or three exceptions, how many centres are there that could muster enough physicians that on the death of a member could pay the widow even $2,000 or $3,000, granting the assessment would be $1 or $1.50 for each death?

Mutual Life Assessment Companies have been formed time and again, and nearly as often have they led a precarious existence, finally dying of inanition. What *is* the remedy? At present there is hardly a town of any size but what has those boons for all mankind—physicians as well as mechanics—building associations. Let a member buy two shares of an association that has $1,000 shares—many are only $500. He deposits his $2 a week, commencing, say, the 1st of January or July. After paying in twenty-six weeks, and he has had his dividend added to his deposits for the six months—declared on the 1st of January or July—let him draw out $50, which will about pay a semi-annual premium on $5,000, assuming the insured is anywhere from thirty to thirty-five years of age. I have reference now to what, in insurance language, is known as "old-line insurance," non-forfeitable, payable at death. Take, for instance, a company like the Manhattan of your city—with abundant assets, well secured, and time-tried—and for every $1,000 insurance he carries, his premiums will be about $12 to $14 every six months. I speak of this company as I am somewhat familiar with their figures, having carried policies with them for several years, making my payments on the plan I herewith suggest. Surely there is hardly anyone in the profession but what can put that much, or double, away every week, and scarcely feel it.

There are many doctors, I am happy to say, who do put $2 a week in building associations, allowing it to accumulate year after year, and when they "buy out" how much have they? At the outside $1,000 or $2,000, according to the amount of the shares, which amount, should he decide to die about that time, can be attached for any indebtedness he may have, before his executors can touch it.

Again, let him die at any time during his building-association membership, he has to his credit only that amount paid in at $2 a week—in one year $104 and interest, same as in a savings bank, only more secure. Let him die at any time during the same period, withdrawing every six months (or twelve if so desired), and he leaves an estate that, for every $2 a week, as suggested, is worth $5,000 that cannot be molested by law.

The practice of medicine to-day, with its many specialties and the numerous free dispensaries and hospitals, cuts deeply into the annual income, of which, after taking out the "family expenses," schooling, horse-keep, etc., there is little left to put away. Hence it behooves us, while in health, to make preparations for our loved ones, and there is nothing more comforting than to know that, with a secure policy for a good round sum, we are ready to meet the summons, come when it may. Very truly yours,

William Judkins, M.D.

216 Race Street, Cincinnati, O.

A New Remedy for Diabetes is phosphorus in doses of about gr. $\frac{1}{60}$, three times daily.

# New Instruments.

## A NEW CLUB-FOOT APPARATUS.

By GEORGE H. EARL, M.D.,

WAREHAM, MASS.

THE apparatus consists essentially of a bent spring, applied to the foot by means of bandages, or to the boot by means of straps, in such a way as to make traction in two directions upon the deformed foot. It does what the hands do in the method known as "hand working."

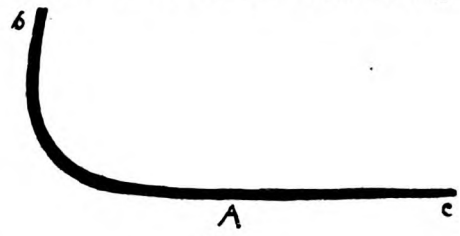

FIG. 1.

Fig. 1 is a view of the spring. Fig. 2 shows the spring applied to the deformed foot. Fig. 3 shows a plan of the spring as fitted to the boot. Fig. 4 is a perspective of the boot with spring and straps applied.

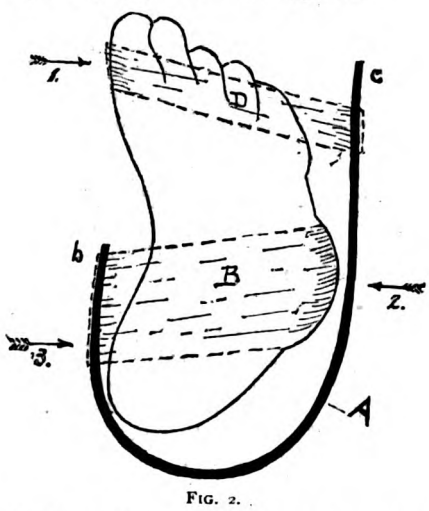

FIG. 2.

The spring is applied by bandaging the short arm *b* to the inside of the foot, just under the malleolus (Fig. 2), the bandage *B* passing over the dislocated bones on the outside of the foot. Then the long arm *c* is bent down

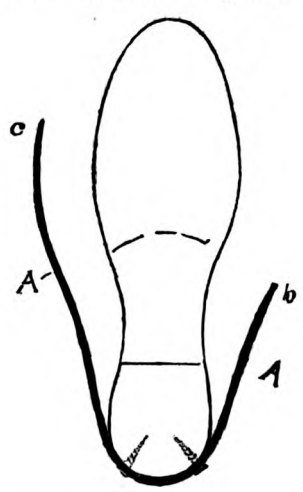

FIG. 3.

along the outside of the foot, and secured by the bandage *D* passing over the end of the first metatarsal bone. Traction is thus made in the direction of the arrows 1. and 2. The arrow 3. represents the fulcrum. After the deformity has been corrected enough to allow the patient to walk on the bottom of the foot, the boot is put on, laced, and the straps *E* and *F* tightly drawn over the ends *b* and *c* of the spring *A* (Fig. 4).

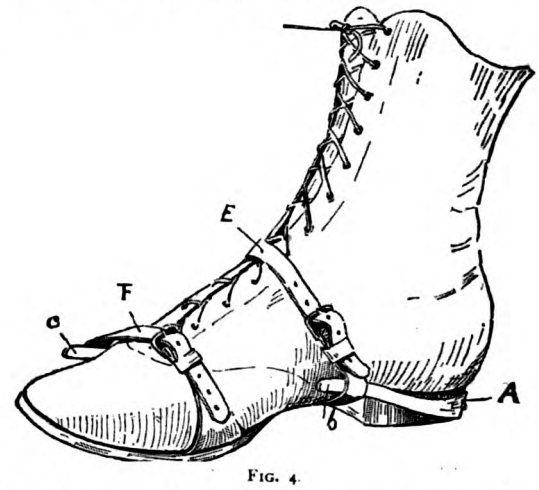

FIG. 4.

The short arm *b*, through the strap *E*, is making constant traction on the dislocated bones on the outside of the foot; and at the same time the long arm *c*, through its strap *F*, is drawing the forward part of the foot around toward a straight line.

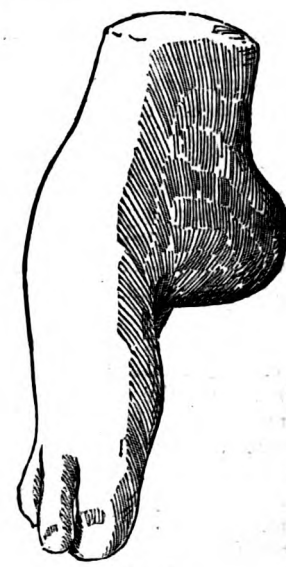

FIG. 5

The splint prevents the foot from turning over while walking, during which the weight of the patient's body is forcing the forward part of the foot up. This latter is

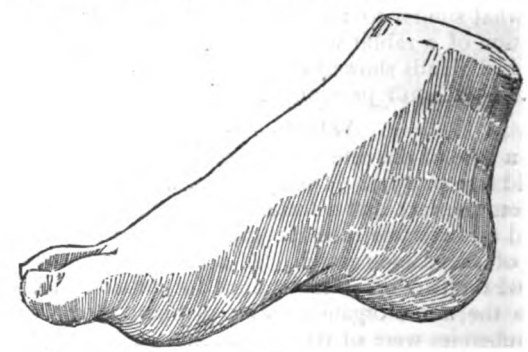

FIG. 6.

the work which "Scarpa's shoe" is especially designed to do, but while on it inflicts severe pain, and prevents the foot from being used.

Figs. 5 and 6 represent two casts, made "before and after." The case is one of congenital club-foot; patient,

twenty-one years of age. Of course, the usual tenotomies were made.

I have neglected to say that the variety was equino-varus, and that the spring is particularly adapted to that form.

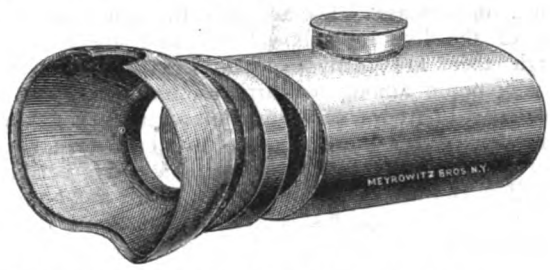
The spring inflicts no pain, can be worn night and day, and be applied by the patient.

## A CONVENIENT ANÆSTHETIC INHALER.

By FRANK DUDLEY BEANE, A.M., M.D.,

NEW YORK CITY.

HEREWITH is presented to the profession a convenient, simple, and effective anæsthetic inhaler, a device evolved from my search for a handy but efficient substitute for the ordinary "cone" or "bag," and one which I have used with uniform satisfaction for several months. Years of experience, including trials of many of the inhalers in the market, convinced me that the bag or cone alone secured rapid, safe, and thorough anæsthesia; that it alone supplied the two requisites, a large supply of the agent and easy regulation of the air-supply. All the inhalers I have thus far tested have proven defective in one or the other or both of these particulars. The inhaler here offered and illustrated consists of a short elliptical copper cylinder, with a rubber hood (mouth-piece) riveted to a metal cap, the latter being removable for convenience in cleansing. The hood-end of the cylinder is encircled by a narrow metal collar to prevent overflow of the anæsthetic in case the cotton becomes supersaturated. The distal end of the cylinder has an adjustable ventilator, surrounded by a dozen small perforations on either side, for regulating the admission of air. A vent in the upper surface of the cylinder, surmounted by a collar and cap, allows of the introduction of the agent used without removing the inhaler from the face. I have found that a packing of absorbent cotton in the cylinder is admirable for holding the anæsthetic; but soft muslin, linen, or other absorbent material, may be substituted.



The advantages claimed for this instrument are:

1. Simplicity. No so-called automatic valves (usually failing to operate) or other complications. 2. A free supply of the anæsthetic, insured by the large size ($1\frac{5}{8} \times 1\frac{7}{8}$ inch) of the hood-cap opening. 3. Easy regulation of the admixed air. 4. Economy of the anæsthetic, as the surface evaporation is very limited. 5. Convenience. It is always ready, being easily cleaned, and occupies but little space in the surgeon's bag.

The instrument, well nickel-plated, is accurately and neatly made by Messrs. Meyrowitz Bros., 295–297 Fourth Avenue, this city.

A NEW OPERATION IN FRANCE.—On July 13th last Dr. Terrier performed an operation which had not been before attempted in France. He established a permanent fistula between the gall-bladder and the duodenum in a woman whose ductus communis choledochus was obliterated, and who, being afflicted with extreme jaundice, presented very grave symptoms. Dr. Terrier had lately seen the patient since the operation. The jaundice had disappeared, the bile passed into the intestine, and the health was excellent.—*Lancet.*

# Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 1 to December 7, 1889.*

WOLVERTON, WILLIAM D., Major and Surgeon, Fort Douglas, Utah. Leave of absence for one month, to take effect on or about December 18, 1889, is hereby granted, with permission to apply at Headquarters Division of the Missouri for an extension of seven days. Par. 2, S. O. 114, Department of the Platte, November 30, 1889.

GARDINER, JOHN DE B. W., Captain and Assistant Surgeon. By direction of the Secretary of War will be relieved from duty at Fort Reno, Ind. Ter., upon the arrival at that post of Captain James C. Merrill, Assistant Surgeon, and will report in person to the commanding officer, Fort Supply, Ind. Ter., for duty at that post. Par. 8, S. O. 279, A. G. O., November 30, 1889.

MCCAW, WALTER D., Captain and Assistant Surgeon, Fort McPherson, Ga. Leave of absence for fifteen days is hereby granted. Par. 3, S. O. 276, Division of the Atlantic, December 3, 1889.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending December 7, 1889.*

NEILSON, J. L., Surgeon. Detached from the New Hampshire, and ordered to the Portsmouth.

BEYER, H. G., Passed Assistant Surgeon. Detached from the Portsmouth, and placed on waiting orders.

SIEGFRIED, C. A., Surgeon. Detached from the Naval Station, New London, Conn., and ordered to the New Hampshire.

HALL, JOHN H., Passed Assistant Surgeon. Ordered to the Naval Station, New London, Conn.

KITE, I. W., Assistant Surgeon. Detached from the Naval Hospital, Philadelphia, Pa., and ordered to the Naval Hospital, Pensacola, Fla.

ROSS, J. W., Surgeon. Detached from the Naval Hospital, Pensacola, Fla., and placed on waiting orders.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 7, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 16 | 7 |
| Scarlet fever | 64 | 6 |
| Cerebro-spinal meningitis | 1 | 0 |
| Measles | 52 | 5 |
| Diphtheria | 80 | 19 |
| Small-pox | 0 | 0 |
| Variola | 6 | 0 |
| Pertussis | 1 | 11 |

THE PATHOLOGY OF PAINLESS WHITLOW.—Dr. Thiriar, of Brussels, publishes some notes of a case of painless whitlow, or the so-called Morvan's disease, which he thinks tend to prove that the central nervous system must be affected in this somewhat rare and ill-understood condition. Only one post-mortem examination seems to have been at all fully reported of a case of this character, and that was of one of Dr. Morvan's own patients (*Gazette des Hôpitaux*, April 30, 1889). Here there were both peripheral

and central nervous lesions, the cervical enlargement of the cord and the nerves of the upper extremities being affected. In the nerves there was a hyperplasia of connective tissue, and in the cord an abnormal development of interstitial tissue occupying the posterior column, the posterior cornua, and probably the central gray matter. It was unfortunately not possible to ascertain whether there existed morbid tubular cavities near the central portions of the chord—the form of lesion styled syringo-myelia—which Dr. Thiriar believes to be the condition to which painless whitlow is due. His patient was a woman aged sixty-six, who six years previously had had a severe bruise on the left thumb, which caused a great deal of swelling, which swelling had never entirely disappeared. Fourteen months before her admission the first two phalanges of the ring-finger of the right hand became swollen and painful, ultimately opening and giving exit to some pus. A year later the left thumb again became painful and increased in size, and after a time broke and gave vent to some pus. Since that time there had been very little pain from either of the whitlows. On examination the lymphatic glands on both sides of the neck and in both axillæ were found to be inflamed, and the upper arms were both considerably atrophied and wanting in sensibility. There was no pain or tenderness in the neighborhood of either of the whitlows. The theory proposed by Dr. Thiriar to account for the second whitlow, which came on without any apparent cause, is that the old injury to the left thumb, which was never cured, set up an ascending neuritis which was followed by syringo-myelia, and probably then by descending neuritis on the right side.—*The Lancet.*

Promoting the Spread of Scarlatina.—At the Hygienic Congress in Paris, Dr. de Valcour related that a death having taken place from scarlet fever at an hotel in Monaco, the room was relet to another tenant the next day, and he likewise died of the same fever. It was not till a third case of scarlet fever occurred in this room that the hotel was closed and disinfected.

The Pathogeny of Hemorrhoidal Disease.—In course of a paper on hemorrhoidal disease Dr. Bodenhamer (*The New York Medical Journal*, January 12, 1889) says that the chief predisposing cause of hemorrhoids in the human subject, according to some authorities, is an anatomical one; and, in order to fully estimate the importance of the subject, this cause must be explained anatomically, which is the more necessary inasmuch as just the reverse of it obtains in quadrupeds; and in this explanation regarding the large vascular supply to the rectum, it will be perceived that hydraulics plays the most important part.

Anatomists know that in the inferior portion of the rectum in the human subject a large number of hemorrhoidal veins exist; these veins are comparatively of large size; they occupy a peculiar depending position; and they receive but little support from the loose cellular tissue which surrounds them. Together with the foregoing facts we must consider the entire absence of valves in the depending plexus of the vena portæ. These several conditions of the veins of this part consequently tend to a retarded or sluggish circulation, the blood being more or less detained in them and favoring stasis. Whenever the body is erect, the blood therefore accumulates in these veins, so that under the most favorable circumstances they are subjected to more strain and pressure than any others of the body, and, in consequence of the want of valves in the portal system, the whole weight of the column of blood in them reaches from the liver or the heart without any interruption downward. These several circumstances act no inconsiderable part in the pathogeny of hemorrhoids. They necessarily give rise either to hemorrhage, vascular turgescence, hyperæmia, congestion, or hemorrhoidal tumors. Indeed, any mechanism whatever which opposes the free circulation of the blood in that hybrid blood-vessel of the liver, the *vena portæ*, may prove a predisposing or an efficient cause of the hemorrhoidal disease. According to authority, therefore, the depending situation of the veins of the portal system must always be a predisposing cause of hemorrhoids in man so long as he maintains the erect posture. The absence of this cause in quadrupeds because of the horizontal position of their bodies is not, in the opinion of the writer, sufficient alone to prove that they are on this account entirely exempt from hemorrhoids, as some authors maintain; but this cause may be a real one, so far as it goes, and have some bearing on the fact that animals are not subject to hemorrhoids.

Effects of Heat on the System.—A series of articles on tropical and subtropical climates has been published by Dr. Cullimore in the *Medical Press*. Regarding the effects of heat on the human system the author says that they differ materially according to the duration of residence, and, therefore, also, as regards travellers and permanent residents. At first, and particularly in the hot season, the functions of respiration and circulation are considerably increased, as is also the vital capacity of the lungs. The circulation, as shown by the greater power and frequency of the pulse, is excited to a febrile or semi-febrile condition; the temperature of the body being in some instances heightened, at least for a time. The appetite and spirits are good, and the capacity for enjoyment and travel as a rule remain unimpaired. After a certain sojourn or period of residence, ranging from six months to a couple of years, this state of exhilaration and excitement ceases, and the new-comer begins to approach somewhat the condition of the indigenized white man, and if he remains, say for nearly a lifetime, without disease, that of the native himself. He has seen some few Europeans in India who could with impunity set the sun at defiance, and one, at least, who was not a teetotaler, who could do so without the aid of umbrella or hat. The vital capacity and respiratory movements become lowered, the pulse, though perhaps more frequent, loses its tension, the heat of the body assumes the normal condition, the plumpness and rotundity, the weight, the firmness of the body diminish, and the excretions, as the urea and carbonic acid, decrease. The action of the skin is increased. That of the liver and bowels at first are increased, though there are many exceptions, constipation being not uncommon among new arrivals, particularly on the West Coast of Africa. The amount of urine is lessened, the process of digestion endeavors to adapt itself to the novel surroundings, the appetite gradually becoming languid and in need of stimulation. There are, however, here also many exceptions. There is prostration of nervous energy and lack of mental activity, not, however, due so much to the influence of heat, unless severe and continuous (above 84° F.), as to heat and excessive moisture. In subtropical and tropical Australia, though the heat is considerable, it is dry, and the go-aheadism and mental capacity of the colonists are proverbial. In damp, low-lying countries the reverse is the case, for not only are the natives degraded and apathetic, but horses and sheep languish and die. As regards active disease, while we recognize great and continuous heat, particularly when associated with extreme moisture, as its main predisposing cause in the tropics, it is to the chilling effect of variations and oscillations of temperature, generally accidental, relatively greater in tropical than in temperate climates, of heavy rains, inundations, extensive marshes, and uncultivated jungles, and, according to some authorities, emanations, therefrom, that is to be attributed the main exciting cause of disease. Sudden falls and high diurnal ranges of temperature, cold winds blowing, and perhaps rain falling, on a sleeping and perspiring body, rapid alternations of heat and cold, are more favorable to disease than a climate with a steadily high thermometer. Suitable clothing and careful attention to the erection and site of the dwelling, to sanitary and individual precautions and management, will, however, in great measure enable us to prevail against the former, while with the latter we are almost

powerless to contend. We may alleviate its attendant discomforts, and even by exercise and attention to diet, etc., stave off its ultimate results, but eventually tropical anæmia, with or without a certain amount of acclimatization, with attendant racial deterioration, lays hold of the system, and the healthy European, or, at all events, his children, assumes many of the mental, moral, and physical traits of the half-caste, and even of the native himself.

Monks as Physicians in the Middle Ages.—Fechin, who figures as the first presbyter named in the Third Order of Irish Saints, according to the famous catalogue given in Archbishop Ussher's "Britannicarum Ecclesiarum Antiquitates," is an interesting example of the circumstance, brought out into strong relief by Montalembert, that the early mediæval monks were the depositories and practitioners of the best medical knowledge of the time. His sphere of activity was mainly in the West of Ireland, and according to Archdeacon O'Rorke, the historian of the County Sligo, leprosy was the disease the saint was most frequently called in to cure. At Fore he was one day begged by a loathsome leper to take him in charge, and Fechin, having carried him on his back to the monastery, left him in the hospital and consigned him to the care of Themaria, wife of King Domnald, who, being promised a heavenly crown in recompense, undertook the unpleasant task. The Queen tended the patient devotedly, and she had her reward; for, so the chronicle runs, "next day, when the saint was going to the hospital, he saw a globe of fire ascend toward heaven from the roof of the building, and on entering the sick-room found that the man they had been nursing, and who had departed in the form of fire, was no other than our Lord Himself—the whole occurrence illustrating the truth of the words, 'Inasmuch as ye did it unto one of these the least of my brethren, ye did it unto me.' In going away the leper left behind a staff and a lump of the purest gold, with directions to the Queen to give them to Fechin, which she did, and the staff became the famous *Bachal Fechin*, with which the saint is supposed to have performed many miracles through life, and which was held in great reverence after his death; but the gold he employed in building hospitals and in other works of charity." Skilfully disentangling this and such-like legends from their mythopæic drapery, Archdeacon O'Rorke accumulates a mass of evidence, corroborated from other sources, which makes it clear not only that the chief, if not the sole, practitioners of Ireland in the seventh century were monks, but that the disease they were most commonly confronted with was leprosy, wrongly supposed to have been first brought into Europe by the Crusaders.—*The Lancet.*

Fraulina Scorbilis in Dysentery.—A correspondent, referring to a paragraph on this subject taken from the *Avisos Sanitarios*, suggests that there was an error in the original notice, and that the writer probably meant Paullinia sorbilis or guarana, the use of which in the treatment of dysentery is by no means a novelty.

Salicylic Acid in the Treatment of Malignant Scarlatina.—Dr. Shakowaki writes that he has administered salicylic acid with the greatest success in one hundred and twenty-five cases of grave scarlatina occurring in children, the mortality being reduced to three and one-half per cent. Ordinarily his method of administration was in the form of a mixture consisting of one part of salicylic acid to 75 parts of water, and 30 parts of sirup of orange-peel, a teaspoonful of this being given every hour during the day and every two hours during the night. He writes that under the influence of this remedy the temperature is rapidly reduced, in certain cases even at the end of forty-eight hours, the temperature falling four degrees. Habitually all traces of fever disappear after the tenth day of the disease. Nevertheless, the author advises to prolong the treatment for some time longer than this in progressively decreasing doses, so as to avoid any danger of relapse. Through the use of this remedy the author believes that he has avoided the most serious complications of scarlatina, such as uræmia, anasarca, and diphtheria. He claims that this medication will only be ineffectual when given too late—that is, after the fourth day of the disease, or when there exists some grave chronic complication.—*Therapeutic Gazette.*

The Disinfection of Books.—The Boston Health Board has ordered that the public library ticket, held by any person in whose family a case of contagious disease has occurred, be stamped so as to show the presence of such disease. All books returned with a card so stamped are to be disinfected, and no other books can be taken out on this card until an official notification is received that the danger of contagion no longer exists.

Glycerine Soap Suppositories.—Dr. Schaffer recommends the use of suppositories cut from a cake of glycerine soap as a substitute for glycerine enemata. The soap is said to contain thirty per cent. or more of glycerine, and the remedy is as effectual in this form, he claims, as it is when used pure.

The Ideal Orthopedic Surgeon.—Orthopedists have been in the past very prone to run in ruts, and have made very slow progress. They have many times degenerated into mere mechanics and have deprived themselves of the right to be called surgeons. While I believe the orthopedist should be eminently conservative, I do not believe that conservatism consists in refusing to operate. The greatest obstacle to the rapid advancement of orthopedic surgery to-day is the tendency of the general surgeon to operate upon every orthopedic case that comes in his way, while the orthopedist too often refuses to operate, applying an apparatus to every case. Between the man who operates upon everything and the man who operates upon nothing the poor cripple has a hard time of it, and orthopedic surgery is brought into disrepute. To my mind the ideal orthopedic surgeon is he who exercises the greatest judgment in drawing the line between the cases that require operation and those that do not, who is equally skilful on the one hand in applying the knife and on the other in applying proper apparatus, and who is without prejudice in either direction.—Dr. J. E. Moor, in the *Northwestern Lancet.*

Intrapleural Injections in Pleurisy.—Dr. Juhel-Renoy recommends the use of intrapleural injections of a one per cent. solution of zinc chloride in the treatment of pleurisy. After evacuation of the serum he injects very slowly a small quantity of this solution, withdrawing it at the end of ten or fifteen minutes. Before the injection the fluid is boiled and then cooled to a temperature of about 95° or 100° F. He claims that by this method the duration of the disease is materially shortened.

He had Quite a Bill at the Druggist's.—The *Tocsin* gives the following particulars relating to the physicking of a patient in the olden times, the good old times, when people took physic and plenty of it, firmly believing that it did them good. The individual in question, Mr. Samuel Jessup, died, May 17, 1817, at Heckington. He was defendant in a trial for the amount of an apothecary's bill at the Lincoln Assizes. The evidence at the trial gives the following details: In twenty-one years (from 1794 to 1816), he took 226,934 pills, supplied by a respectable apothecary in Bottlesford, which gives an aver age of 10,806 pills a year, or 29 each day. In the last five years preceding 1816 he took the pills at the rate of 78 a day, and in the year 1814 swallowed not less than 51,590. "Notwithstanding this," says the *Tocsin*, "and the addition of 40,000 bottles of mixture, besides juleps and electuaries, set out in fifty-five closely written columns of the apothecary's bill, he lived to the age of sixty-five years."—*The Hospital Gazette.*

A New Operation on the Urethra.—Dr. R. Gersuny, of Vienna, who some time ago transplanted a rabbit's nerve into Professor von Fleischl's arm, has recently

devised a new operation for incontinence of urine. In a case of epispadias in a girl, the urethra admitted the little finger, and had the form of a funnel, one centimetre long; the clitoris was cleft; there was complete incontinence of the urine. At fourteen years of age, the mucous membrane corresponding to the cleft was excised from the anterior commissure of the labia up to the neck of the bladder, and the edges of the cleft were sutured. The girl was then operated on by Professor Pawlik, according to his own method, but the patient could hold her water only for an hour when sitting; on walking or standing, she could not do so at all. Five years later Dr. Gersuny operated on the patient, who was then nineteen years of age, by laying bare the urethra as far as the arcus pudendi, twisting the external orifice of the urethra to the extent of a semicircle (180°), and suturing it in this position. The success was incomplete, and this was also the case after a second operation, in which the urethra was further twisted to the extent of 90°. Four weeks later a further twisting, to the extent of 180°, was effected. This proved completely successful. The external orifice of the urethra was turned round to the extent of one circle and a quarter (450°), and the urethra was twisted in its longitudinal axis in the form of a screw. After the last operation there was retention of urine (ischuria) for three days, so that the patient had to be catheterized. From that time she could micturate spontaneously, and the urine never passed involuntarily. The capacity of the bladder was at first from 100 to 200 cubic centimetres. Evacuation took place under strong pressure, and lasted for ten minutes. This condition improved rapidly, and after five months the patient could hold her water for five hours in any position; then she was attacked with strong tenesmus, and evacuated, without effort, half a litre of urine; the act, however, still required about four minutes. The progressive improvement was the result of the gradual dilatation of the bladder and the strengthening of the detrusor urinæ. The operation of Dr. Gersuny is indicated in those cases in which the sphincter of the bladder is quite powerless and the detrusor intact.—*British Medical Journal.*

A Precursor of M. Brown-Séquard.—M. Megnin publishes, in the *Journal des Connaissances Médicales* of August 15, 1889, a note in which he announces that he has discovered, in a book entitled "La Chasse au Chien Courant" (p. 202), published in 1838 by Elzear Blaze, a passage couched in the following terms: "When you have the fortune to kill a wild boar, do not throw away the testes (les suites), they will prove very useful to you later. If perchance the desire to marry seizes you at an advanced age, when only vague hopes of becoming a father remain to you, *vous savez?* There are moments when one has confidence in himself, then everything vanishes like a phantom. *Eh bien!* the testes of your wild boar, dried and powdered, diluted with broth of an old cock, and swallowed fasting, by you and your spouse, will have a marvellous effect; children will be born to you every nine months, and you will be obliged to come to me asking for another recipe which will bring about the former condition of affairs." I give this recipe to you just as I have found it in the works of a learned physician. "Magna est uxoratis inquietudo et animi perturbatio prole sterilis existere: propterea, ut tanto infortunis liberentur prolemque habeant, per aliquot dies jejuno stomacho vir et uxor cum jure galli veteris testiculorum apri in umbra exsiccatorum pulverem capiant; profecto brevi tempore optatum adispicentur, ut in multis sterilibus ex quacumque causa non semel expertum est." (Julii Cæsaris Baricelli, à Sancto Masio, doctoris medici Hortulus Genialis. Genovæ, 1620.) Répertoire de Pharmacie. [This seems to be a coq-à-l'âne.—Ed.]

Thermo-palpation.—It has been known for some time that there is a difference in the surface temperature of the body corresponding to the organs underneath—that is to say, the temperature is higher over the lungs than over the liver or the heart. From a communication published in the *Orvosi Hetilap*, one of the chief medical journals in Hungary, by Herr Jonás and Dr. Benczúr, it appears that this fact is available as a basis for a novel method of physical examination which may be styled "thermo-palpation." These observers say that it does not require any peculiar sensitiveness of touch or any special education to appreciate the difference of temperature on passing the fingers over the surface of the body from the situation of the lungs to that of the liver, and that patients themselves, and students who had not yet learned percussion, were quite able accurately to detect the height of a pleuritic effusion by the difference of temperature. Diseased and healthy organs can be mapped out in this way by going over the surface, first, say, downward and then upward, when the line of demarcation will be distinctly felt. The general principle appears to be that organs containing air, such as the lungs and intestines, permit of greater surface warmth over them than more solid organs, such as the heart, liver, spleen, etc. Of course, instead of using the fingers, a differential thermometer may be employed, and much slighter differences may be recognized than is possible by the touch alone.—*The Lancet.*

Contamination of Well-water.—A writer in the *Annals of Hygiene* for October, 1889, relates a curious fact which may tend to shake the confidence of many country residents in the purity of their water-supply. It is generally supposed that there is no danger of contamination if the cesspool is at a lower level than the well and at some distance from it. But in the case to which the writer refers there were two wells on the place, separated a distance of two hundred and seventy-three feet from each other, and one being fourteen feet lower than the other. Yet when water was pumped from the upper well the water in the other was very decidedly lowered, showing that there was quite free communication between the two. If the lower one had been a cesspool, the water in the upper well would doubtless have been contaminated.

The Brain and Moral Culture.—Under the title of "Gehirn und Gesittung," Professor Mynert, of Vienna, read a paper before the last meeting of the German Association of Naturalists and Physicians, in which he considered the brain as an inhibitory apparatus against the lower and more instinctive natural impulses. The higher its development the greater is the tendency to subordinate the particular to the general, and even in the lower animals we see a high state of social growth, as in the communities of bees and ants. In the development of the human individual, we see in the infant, a being entirely wrapped in its instincts of self-preservation, the "primary ego" is predominant, and the child is an egoistic parasite. As development goes ont his stand-point is passed, conscience assumes its priority, the brain acts as a check on the purely vegetative functions, and the "secondary ego" takes precedence over the primary one; and this is the general order of society we designate as civilization or social order (Gesittung). If this inhibition becomes weakened, as in progressive paralysis, then we see the disordered predominance of the natural instincts or impulses, and when it is totally lost the individual is in the position of a criminal, who opposes the ethical order of society—a parasite, and one of the worst kind, one who not only lives upon his host, but destroys him in so doing.—*American Journal of Insanity.*

New Remedies for Whooping-cough.—Dr. Andeer (*Centralblatt f. Med. Wissensch.*) gives resorcin in one-half to two per cent. solution, according to age. Half a wineglass is administered several times daily. Dr. Stepp (*Deut. Med. Woch.*) gives one to seven drops of bromoform in water three to four times daily. The bromoform should not have any red color, as it then contains free bromine and is irritating.

### RELATION OF MEDICINE TO THE PROBLEM OF SOCIALISM.[1]

BY WILLIAM MECKLINBURG POLK, M.D.,

PROFESSOR OF OBSTETRICS, GYNECOLOGY, ETC., IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

MR. PRESIDENT, LADIES, AND GENTLEMEN: When I received the notice of my appointment as your orator upon this occasion, my impulse was to write at once and decline the honor. I could not see that my life or my opportunities had been such as to enable me to reach the high standard which should be obtained upon the occasion.

If such was my first impulse, you can easily comprehend how greatly it was intensified when I fully understood what had been said here in these halls by those whom you had honored in the past. Were I to mention but one name, and that the name of John W. Draper, no one within the sound of my voice could question the fitness of the sentiment.

Because he was a "Doctor of Medicine," who impressed himself not only upon the very foundations of our science, but in his work upon "Intellectual Development" did so much to impress layman, physician, and priest with the grandeur of medicine, grand not only in its relation to individual man but in the influence exerted by its disciples in the preservation and revival of learning, a preservation and a revival about which clusters all that is worth having in the life of to-day.

The ripe scholarship involved in his productions was fittingly offered here, and such is my estimate of your position, your influence, your mission, that nothing short of such products is deemed sufficient by me for such an occasion as this. You can excuse me, then, when I repeat that the realization of my task oppressed me. But I trust to your leniency, and will pass on to the fulfilment of my office as best I can.

The selection of a subject of discourse is by no means an easy task where the audience is as heterogeneous as prevails upon the occasions of your annual meetings. A physician can always speak to a company of physicians, but when the laity enter he feels the restraint of his technical training.

Your orators have met the difficulty in many ways, so that few questions of general yet professional interest have been left untouched. Medical education has received the most distinguished consideration, the advances in medical knowledge have been ably presented, our history, ancient and modern, has been unfolded, and the gifted Roosa, casting the horoscope, has supplemented Lord Lytton by differentiating for us our position with the "coming man." What, then, is left for me to-night? The Preacher has said, "There is nothing new under the sun." The man with an absolutely novel idea is a phenomenon not often seen in history or literature. All of us are borrowers, and it has been justly said that if ideas were refused recognition because something similar had been propounded before, there would be a pretty outlook for civilization. Certainly there would be a depressing outlook for most speakers were they not permitted to seize upon some topic of general interest, and endeavor, by rearrangement, perhaps by developing some fresh association, to offer something in return for your patient presence before him.

[1] Being the Anniversary Address before the New York Academy of Medicine.

It is in the rôle, then, of one who presents a familiar subject in a new association that I appear to-night.

I have stated that I would speak upon the relation of our profession to some of the questions of the day. I shall modify this and say "the question of the day." No less an authority than Professor Seelye has but recently said, "There is one question of our time toward which all other questions, whether of nature, of man, or of God, steadily tend. No one will be likely to dispute the affirmation that the social question is, and is to be, the question of our time." In my own case the impression created by this remark was fixed and intensified by the perusal of a small volume called "Our Country: Its Possible Future and its Present Crisis." The broader bearings of social questions had been too far removed from the busy routine of my daily life for me to give more than a passing notice to it, and had it not been that I saw certain phases of the question which were touched somewhat nearly by us my interest in it would have remained general.

Believing, then, that we have something more than a general interest, I propose to ask your indulgence while I endeavor to trace the relation of medicine to this social question.

We should be encouraged to this inquiry by the wide-spread interest which it is evoking. One of the surest evidences of the truth of this assertion is to be found in the frequent and able discussions and dissertations upon it in the current literature of the day. Politics is making of it a factor in government, and the Church, conscious of the moral aspects of the question, is fast awaking to the necessity of an active censorial position on its part.

The social question may be defined as an inquiry into the status of the orders of civilized people, and their relations one to the other in the economic arrangements of the social system. The recent growth of the inquiry is due to the conviction that the relations are becoming dangerously abnormal through the action of preventable causes. These causes are being gradually defined and remedies are being sought for by many of the best minds of the day.

As is to be expected in such a question, there exist wide differences of opinion. But upon one point all appear to agree, namely, that discontent with the present arrangement and relation is wide-spread, and that this discontent is assuming the nature and proportion of a defined class-question upon which the two great orders of present society are arraying themselves, the one in opposition to the other.

The question assumes phases which differ somewhat in different countries according to the kind of government which prevails, and, as enunciated by the class in whose interest it was first raised, is called "Socialism." It is the belief of many, and history seems to confirm it, that in Socialism we but witness a continuance of that process by which man as a whole is being ever lifted upward. Providence, ever careful of its products, seems to will it that the classes into which man arrays himself shall never be too far separated, and when this interval reaches certain dimensions forces are set at work by which its component parts are made to approach one to the other, always with the result of lifting the mass upon a higher plane, the most striking change being developed always in the condition of the lower order, which is continually being levelled upward. Examples of the process stand out in every epoch.

To go back no further than nineteen hundred years, we

find a movement beginning in an obscure village of Palestine which, extending itself over the lower classes, dominated the Roman empire, and subdued every conqueror who successfully overran the realm. The underlying principle was betterment of the lower order, and in that far-reaching agitation it is not difficult to discover the greatest step in social evolution recorded in history.

We see it again in the Reformation, and its latest imprint stands before us in the tragedy of the French Revolution.

"Socialism," however, was scarcely a formulated creed until about the beginning of this century. The stimulus derived from the French Revolution initiated it, and this, together with the growth of the democratic idea of government as witnessed in this country, may be said to have developed it. Realizing that little could be accomplished save through political power, its first aim has been toward securing the ballot. Its history so far has been largely made up of successful efforts to that end, so that to-day in most civilized countries political power in greater or less extent is practically conceded it. In this country we see the highest development of its political effort, and there can be no question that, conscious of its power, it is making ready to advance toward the end and aim of its existence. To-day it practically stands organized for self-protection; its next step will be one of aggression.

"Socialism," then, is the expression of the lower orders of their discontent with the conditions of their life, and is the formulation of its ideas and purposes as to the remedy. It draws the line with sufficient clearness between itself and its opponent, so that no one need be ignorant of its purposes.

The question at issue is being gradually narrowed to that of property rights, the term property being made to cover everything out of which the man meets his daily wants, whether it be his money accumulations, his hands, or his brain. It is interesting to note that while the successful working of republican government in our country stimulated to a tremendous degree the growth of Socialism in Europe, yet Socialism has never until the present day been able to assume a definite shape in our midst. Our peculiar position has undoubtedly been responsible for this immunity. The first aim of Socialism, political power, was conceded by us at the outset, and as for the question of "property rights," it could have no hearing.

In fact in this, a new country, such was the breadth of resource, such the beneficent influence of soil and climate and of government, that all the conditions securing content so far outstripped those of an opposite tendency, that anything like general dissatisfaction in any one class of the population was an impossibility. Profit and prosperity being so easily in reach of all, the complaints of the malcontents were safely set down to laziness or viciousness. A most curious condition of affairs has been evolved, however, from what was apparently the most fortuitous combination of human circumstances. The fundamental principle of our system was declared to be the freedom and equality of man in the pursuit of any of the just purposes of life. Our domain being large, and population relatively sparse, immigration was successfully encouraged. Ignorance being recognized as a threat to the State, education was amply provided for and carefully fostered. Out of these sprang that marvellous manifestation of human force seen in American energy. Now the doctrine of equality can mean but one thing, namely, the freedom of all to compete for the prizes of life; and certainly, here with us, it has produced an amount of material advancement such as the world never before witnessed. The pace at which we have moved has been indeed tremendous, but while demonstrating some of the advantages of freedom, it has come to develop a well-recognized law of nature, the survival of the fittest. It begins to show that to the strong literally belongs the victory. It is interesting to note, too, that this seems to be the case in both of the orders into which our society has been divided. Already combinations for the purpose of destroying freedom in competition are assuming shape in each. It is only necessary to point to the restrictions upon imported contract labor and those upon apprenticeship sought for in one class, and the combinations to check production and expenditure in the other. It would appear, then, that the doctrine of human equality was being worked out among us to a point which will demonstrate that it has inevitable natural restrictions.

The suddenness with which this apparent failure of the practical application of the doctrine has come upon us is mainly due to the abnormally rapid increase in our population through immigration. For this increase has been mainly in the order which has the least in the shape of worldly possessions, and therefore feels most the pressure incident to its acquirement.

Instead, therefore, of a limited discontent, which could safely be put down to laziness and viciousness, we find ourselves possessed of a rapidly spreading dissatisfaction with the present state of our economic conditions, which can be traced to the strain put upon man's resources by the free and active competition for what there is to be had of profit and prosperity in a rapidly increasing population. And this is not all. When you educate a man you encourage him to institute comparisons; he institutes them, and when applied to himself content is not always the result. One would suppose that the same education which enables a man to institute and apply comparisons would take him higher than mere discontent suggests. This is true only so long as he feels that his natural powers are equal to the demands of his situation. And no matter under what conditions he lives, the moment that his powers of comparison prove to him the insufficiency of his natural forces in the struggle which society lays upon him he will begin to agitate for a change which will neutralize his disability, one, in fact, that will admit of a wider application of the doctrine of equality than is contained in the laws of the system under which he may live.

Here in America there is a fear that education may not enable him to reconcile the incongruities which his observation tells him exist between the facts of his daily life and the assertion upon the equality of man contained in that corner-stone of his Government, the "Declaration of Independence." Such an one is apt to see in the doctrine of the equality of man a panacea for economic inequalities which he sees about him. And if they touch him sorely a selfish interest will lend zest to his desire to apply it to his betterment. But the essential point for our purpose is that he is being continually told by those who seek his vote that his Government was initiated and constructed upon that idea, so that, whether there be wisdom in it or not, whenever the inequalities of his situation in the social or economic order press heavily upon him he will contend for its application, the result of the contention depending, of course, upon the strength and the efficiency of his combinations. We have seen that Socialism is a question of property right: the term property being used to cover all that a man possesses with which to meet the wants of his daily life, whether this be his hands, his brain, or his surplus (that is, his invested or hoarded money). There are two ways for a man to better his property condition. One is to get it from those who have an excess above their necessities, by taking it by force, either directly or else through law enacted to that end. The other is to get it from those possessed of the excess, by the exercise of superior mental or bodily skill in untrammelled competition. But it must be remembered that the holder of the surplus is possessed of three of the elements of property as defined. And such is the preponderating weight of surplus that it turns the scale in favor of its possessor. It will be recalled by all of us that a war but recently swept over this country which, in the abolition of slavery, emphasized the inalienable right of man to the absolute and untrammelled possession of his own hands and his own brain.

These elements of property may then be put outside the field of contention. There remains but one other, "Surplus." The Socialist, however, virtually argues that the only property right inherent to man is his hands and his brain, that surplus is a tyrant to be controlled, to be directed to the general rather than to the individual good. No one can say how he will do this, but that he will attempt it is self evident.

Now surplus was never so clearly defined, so definitely accentuated as the controlling force in man's affairs as it is to day, the mass of men lying almost in grovelling attitude before the golden calf. It would appear, then, that the destiny of surplus was in its own hands.

Resolving surplus into its equivalent, namely, its possessor and controller, the upper order, we see at once between what forces the issue is being formed. It is quite evident that Socialism has no intention, for the present, of permitting the question in open politics; it looks rather as if its purpose was to work parties toward its position by using its combined vote in one or the other as it sees its interest. Practically this constitutes with us, so far, its political organization for its economic ends. It is fair to assume that the question will ultimately reach a just solution, but it is evident that there will be much friction in the solution of its various phases. With us so far it has been free in the main from the violent acts which have attended its development in other countries, and many think that, because of the nature of our institutions, this freedom from disorder will be maintained. Others, on the contrary, feel because of our very freedom from governmental restraint that the question is almost as full of explosives as was that which culminated in the French Revolution; for, like that, it is a class question entering every household in the land. It may be nonsense to compare the lower orders of this country with those of France one hundred years ago, but it is as well to remember that human aspiration was the life of that movement, and human aspiration is certainly at the bottom of its continuance in Socialism. Someone has said that there is a popular faith among us that God takes care of children, fools, and the United States. It begins to look as if we might be thrown upon our own resources. Fortunately we have been liberally supplied; it is only necessary to look to the proper employment of our means.

It goes without saying that this question is primarily one of statecraft. It is grand politics, the province of the statesman.

But so was Christianity, so was Mohammedanism, and if I mistake not there are excellent proofs of the influence of medicine in propagating the one and in civilizing the other. If you will turn to the delightful pages of Draper's "Intellectual Development of Europe" some suggestive facts will be found concerning the influence of the schools of medicine in turning the Arab conqueror to ways of peace and intellectual culture, and in another chapter will be found statements full of food for our thought concerning the propagation of Christian ideas through the action of a certain Perabolani.

Your orator, John Watson, in his sketch of the "History of Medicine," delivered here some years ago, told you of the attitude of medicine in those days. How in the person of the Perabolani it worked as an engine of Christian propagation, and how in the person of its temples of learning it stood upon the side of the pagan. How in the contest that finally witnessed the triumph of Christianity we were rent in twain, our culture deposed, and our ignorance installed as directing influence in our affairs. For us, then, there is both warning and encouragement in turning the pages of history. The state must rest upon the intelligence of its people for the wise solution of the questions which vex it, especially upon the intelligence of the leading orders of its society. Are we not one of them and do we not stand out more prominently than ever before as a recognized force in the social system of the day? As we have borne no small part in great questions of the past, let us see that we be not blind to our mission of the present.

In viewing this mission, let me again remind you that the honest believer in "Socialism" looks upon the fulfilment of its essential principles as not only possible but unavoidable; for he regards it merely as a phase of that evolution process through which man in his entirety is being carried ever onward to the more perfect state of existence. And yet we cannot shut our eyes to the fact that this is far from the position assigned it by the interest against which "Socialism" must operate, if it act at all; and it is easily seen, whether it prevail or not, that from this difference dangerous friction must result. Certainly, it becomes us to inquire if this friction may not be lessened at some points through our efforts.

The content of a people is dependent upon their physical well-being, the first essential being a healthful life. The conditions necessary are at the command of the one order, so that they have but themselves to blame if it is not allowed. But how is it with that other which is forcing the social question to the front? Is there another element in any civilized land, but especially in this, which is better placed than ours to properly answer this question? As I look over this audience I venture to say my eye falls upon a body which, through its members, touches every class. Yes, every person in this community. And this community, what is it? Is it not the exponent, do we not find in it the very essence of that question of socialism which is beginning to press so hard upon us? In this seething mass of humanity, with its pleasures on the one hand, its sufferings on the other, its aspirations here, its lost hopes there, we have a very epitome of the whole human race. And as we pass from home to home, from tenement to tenement, do we find the conditions of healthful life present or even possible with the majority of our population? It has been said that our profession is the buffer between the colliding forces of society; and we are so because as individuals we hold more of their confidence than any other class. Are we doing our duty in this position? if not, in what are we failing? Gentlemen, there is a woful ignorance, perhaps a woful blindness on the part of the mass of the high order to the physical condition of the lower, and it comes from the fact that they are too busy with their own affairs to trouble themselves about the matter. They will give their money lavishly, provided they are not called upon to give their time. But this problem requires attention as well as money, thought as well as prayer. I take it that in this matter our mission is from the higher order to the lower, from the lower to the higher. How many people in this town really know what are the conditions of healthful life? They have a general idea, but general ideas are not working formulæ. We need working formulæ. The public, both orders, must be taught that much of the discontent lies in the absence of the conditions of healthful life. And then they must be taught to know those conditions, to study those conditions with a view to their introduction and their acceptance. I say acceptance, because it is well to remember that it is as difficult to get the ignorant to apply to himself the laws of physiological science as it is the laws of theological science. In all this it is recognized that theories must vanish, and what is done must be done in accordance with the accepted rules of economy in business pursuits, simply starting with a just interpretation of that law of healthful existence which applies to the condition to be corrected. This is as far in the direction of specification as my time will permit to-night. But, after all, we are here this evening to inquire more as to the relation of medicine to a general question, than its specific application to any one part of it.[1] This is the harder task, but the first step toward it is to ask about it. But will the public heed us? That, gentlemen, depends upon our attitude in the matter. We must drop our ex-

[1] Dr. H. D. Chapin: "Preventable Causes of Poverty," Forum, June, 1889. Alfred H. Peters: "The Extinction of Leisure," ibid., August, 1889.

clusiveness, and understand once for all that we only need speak in plain terms, that plain people can comprehend, upon the practical application of our facts, not our theories. Our facts are plentiful enough, as you well know. In the present social order we appear as teacher, as practitioner. As practitioner, as minister to his ailments, man has always accepted us, but as teacher he has been less receptive. Man always exacted of us more than we could give, namely, eternal life. And failing to get this, he easily became sceptical as to whether we could tell him anything at all about life. Having but a surface knowledge of nature, supernaturalism became his mainstay, remaining his prop until within the days of our own knowledge. And yet while he asked of us the elixir of eternal life, he failed to furnish us the educational conditions essential to a knowledge of the laws which govern even the short life nature assigned him. This perhaps was natural, recognizing as he did that he was to be the material out of which we were to carve our science. Seeking our material as best we could, as nature's disciples, we were often brought to antagonize some of man's most sacred instincts, bringing upon us his suspicions and his wrath. Thus a habit of reticence concerning what we did know has grown upon us, which perhaps may not be misnamed exclusiveness. But the necessity for reticence which so long hampered us is fast disappearing, the conditions essential to our progress are more generally recognized and conceded, and this, together with the decline in the faulty application of supernaturalism, is rapidly changing for the better the situation heretofore existing between our body and the public. We owe our emancipation to the strides made by the collateral sciences, but more particularly to biological and anthropological research; for, after all, ours is but a subdivision of the science of anthropology. Man's curiosity concerning the laws of other life has at last fully possessed him with the desire to know something, yes, all of those that pertain to himself. Quick to avail himself of everything that nature's law could contribute to his pecuniary profit, he is awaking to the fact that that profit can be easiest gained and fullest enjoyed by him who best fulfils in himself the law which nature gave him to live by. And with the dropping of the scales he now begins to see that as the spiritual perfection can only be reached by seeking for, by finding, and by following God's moral law, so physical perfection can only be had by seeking for, by finding, and by following that law which his God has given him to live by when he enters into the land to possess it.

If ever there was an age in which knowledge of the laws of life, of health, and of death were more universally sought for than is this history fails to record it; for education and competitive life have brought the civilized world to our door, so that it may truthfully be said we stand upon the threshold of the golden age of medicine. It is indeed our opportunity, and if we fail to grasp the occasion it will be the fault of just such representative bodies as I have the honor to address to-night. It is as the teacher, then, that I will speak to you. You meet together here from time to time to consider many questions, but there is a wonderful sameness about them all. They relate to the peculiarities of this or that disease, the usefulness of this or that remedy; occasionally a question of ethics frets you, and now and then you vex yourselves about the question of education for medical men. Do you ever much trouble yourselves about the medical education of the great public? Perhaps you think you do this through the medium of your members, and that providing for their equipment your duty ends. Ah! believe me, Academicians, when I say that useful as this office is, it falls far short of a fulfilment of your mission.

Let us take a broader view of our mission than is involved in these processes of mere self-instruction. Let us shake off the exclusiveness of our teachings, and, taking the public more into our confidence, speak directly to it of those laws of life and health which are each day becoming so necessary to it in its present emergency, and which they are eager to receive from us as its recognized expounders.

Drive home to him whose property right is represented by his brain, by his muscle, that his body is his capital out of which his profit must come, and if he consume all of profit he gets from year to year, it is the more important in the economics of his life that he keep his body in the best working order. He hears of chance, of luck; bring it home to him that the luck he loses is lost because of physical defects engendered in his heredity, in the hygienic defects of his daily habits; and put it hard upon him that in the failure of to-day he but sees the paralyzing influence of some infraction of the laws of health yesterday, and that in the conduct of his life to meet his daily wants —in health as in morals—he must accept the dictum, "As we sow so must we reap."

The moralist teaches that retribution follows the infraction of God's law. We can demonstrate it; he cannot, save through us. Go then to Surplus, present it your facts and show it how to turn its thought, its action, to the correction of those evils which in its system press so hard upon the physical condition of those outside itself. Show that with a large part of the brain and muscle of this land, especially of this city, such is its poverty it is almost impossible to secure to itself many of the commonest essentials of healthful life.

Show it, prove it, as you surely can, that from this condition springs that inefficiency, that mental and physical deterioration, that laziness, that viciousness which constitute the blight upon its social system. Lay plainly before it the inevitable reaction of such states of human existence, and in doing it, do it wisely, to the end that we may say, We have met to the fullest the duty which, in the process of social evolution, was laid upon our shoulders, for in answer to the mandate of that first law of nature, we have taught you the way to "self-preservation."

Thus, starting from the basis of those laws for which we stand, let us unfold to man not only his duty toward his neighbor, his duty toward his God, but his duty toward that temple of God which was created when he was born into this world.

---

## CONSERVATISM IN GYNECOLOGY AND OBSTETRICS.[1]

By MALCOLM McLEAN, M.D.,

VISITING GYNECOLOGIST, RANDALL'S ISLAND HOSPITAL; SURGEON-IN-CHARGE OF ST. ANDREW'S INFIRMARY FOR WOMEN, NEW YORK.

In the midst of the enthusiasm incident to an unprecedented progress made in our profession it is no easy matter to maintain an attitude which shall shield us from the imputation of being on the one hand too radical and on the other too conservative.

Recognizing this difficulty, it is with considerable hesitation that your reader has essayed to set down any suggestions which are intended to define between extreme and active interference and cowardly or dangerous inactivity.

Practitioners in obstetrics and gynecology seem to be divided into three classes: First, those who are ever active to interfere surgically, mechanically, apparently assuming that the *vis medicatrix naturæ* exists only in the minds of a few unenlightened individuals who are too slow to appreciate the necessity of bold surgical procedures, and who are not capable of grasping the problems of advancing science. Second, those who, having learned to be passive, depend alone, almost, upon natural changes to effect a cure, who are obstructive to every innovation, who only see virtue in the ways they first walked in—these constitute a large class who would have their profession at a stand-still from decade to decade.

There must be recognized, however, a third class, who calmly weigh the merits of each advanced theory or achievement, putting eagerly into practice that which seems to be

[1] Read at the meeting of the Medical Society of the County of New York, November 25, 1885.

good and condemning that which proves to be worthless; who are ready to recognize the true worth of any method of treatment which brings with it more light and more relief, but who resist temptation to follow blindly in the current of a new excitement simply because great numbers are swayed by conspicuous examples of great surgical achievements. These are they who must act as balance-wheels to the profession, who must limit the enthusiasm of the zealots whose ambitious desires lead them into a fever for "records" rather than to a firm determination to succeed by a careful, conscientious discrimination in favor of the confiding patients. I fear that too few of us, alas! belong to this third class.

On the one hand we see the records of countless exploits with the laparotomist's knife, and we are easily persuaded that, to be modern, we must be bold and dexterous. We must not fall behind in records, if we do in the aggregate number of our cases. A little reading, a little breathing of the laparotomist's atmosphere, whether it be in the operating-room or in the halls of scientific societies, and we are converts to the new faith and boldly enter in. A few short months roll on and we are ready with our "year's record in laparotomy." With pride we point to our scores of successful cases, and we feel convinced that we have at last struck the panacea for most of woman's ills. We become more and more impatient with treatment which entails slow and tedious measures, and too often we forget that cases have been cured by other means than the knife, and that our patients have a right to the benefit of the every doubt.

But another danger confronts us in our experience, which must by no means be overlooked. Trusting to the good fortune of many cases working out their own salvation, we allure ourselves into paths of inaction, of half-hearted belief, of trifling and superficial estimation of the duties before us, and in the falsely assumed guise of conservatism we fail to act when everything declares that delay is dangerous. Those of us who fall into such ways are as full of danger to our patients as are those who plunge recklessly into more active measures.

Such practitioners crowd our ranks with incompetency and stupidity, and see no good in the advances of a newer generation. It is not necessary to portray more minutely that pitiable company—they are to be found everywhere, in city as well as in country, and if they cannot be converted they are to be avoided.

But I feel that special attention and consideration should be given to the new generation of extremists who are filling our profession with their doctrines of radical operative interference in the majority of severe cases which come under the eye of the gynecologist.

When Mr. Tait had his first followers in this country it was at once suggested that this new path of surgery would be, perhaps, crowded to a hurtful extent. One of the first, if not the first in this part of the world, to test the operation known as Tait's, while showing his specimens of extirpated tubes, remarked: "I am not yet prepared to give the operation the broad application given to it by Mr. Tait, but that it has a future I feel assured."

Possessed of rare skill and unsurpassed courage, that distinguished operator has, I believe, still the conviction that a too general application is being made of a radical operation which should only be called for when all other treatment is known to be of no avail. But the mass of the younger gynecologists—impetuous, ambitious, "one-ideaed"—seem bent on bringing great numbers beneath the laparotomist's knife, without anything more than a rudimentary experience, at most, in the use of treatment which does not necessarily involve a mutilating operation.

Men whose opportunities, on account of age, location, or other environment, have been necessarily limited so far as practical experience in medicine is concerned, are willing to believe themselves capable of judging fairly of the conditions demanding an operation which not only exposes life to great peril but, at best, mutilates and deprives woman of an essential part of her organism.

The best surgery, whether it be abdominal or general, is more likely to be done by one whose mature judgment has calmly weighed *all* the evidence in a given case than by one whose predilections stand in the place of knowledge and experience, and impel him to fit the case to his treatment, instead of adapting his treatment to the requirements of his case.

It would appear as though there are various influences which lead so many, in this day, to drift into the fascinations of radical operations, some of which I have already hinted at. Two special influences of different moral tone certainly play an important part in the determination even of the more skilled and experienced operators.

First, the influence upon the mind of *seeing* pathological conditions of the internal organs. Specimens of "cystic ovaries," of enlarged tubes, etc., appeal to the senses in such a vivid manner that we are easily—too easily, I fear—convinced that nothing but extirpation of such tissues can ever effect a cure. And right here we doubtless make serious error. Because we can extirpate an ovary with more or less macroscopical change apparent, or a tube with fluid in it, it is not necessarily true that such appearances, even though they be pathological (which is not always the fact), are evidences of hopeless structural change, and hence demand their extirpation.

This point I wish to insist upon sufficiently to make it emphatic, as I am well convinced that the frequent handling of and seeing these organs in the conditions described has much, far too much, to do with the decisions of surgeons in these matters. Imagine, if you please, the appearance of an inflamed pulmonic lobe—or other organ removed and presented as a "specimen" at our surgical societies. If the same logic were used in reference to these other organs as we find proposed in connection with the disease of the tubes and ovaries we should have to consider it necessary for a *cure* to perform a surgical operation for their removal. Moreover, ovaries that are "cystic" or "slightly cystic" are frequently condemned because they have unfortunately been caught in the act of ovulation, a *physiological* process be it observed. Who ever saw a properly developed ovary without cysts or vesicles in it? What has become of the Graafian vesicle? By what new route is it discovered that nature extrudes an ovule? Yet, if one will take the pains to look over vast numbers of histories, given in the operator's own words, he will observe that the ovary removed was "slightly cystic" and hence had to perish.

It is only a fraction of a century past since tonsils were, almost without consideration, condemned to instant extirpation. Yet after a while it occurred to some thinking men that it was probably carried too far, and then the operation of tonsillotomy took its proper place in surgical practice.

The testicle and its essential adnexa are not infrequently the seat of violent organic changes, and I doubt not, if we could muster up courage enough to procure such an organ by extirpation for a pathological specimen at our scientific assemblies, we might convince many that such a frightful condition of things demanded nothing less than their removal for a cure. Such a specimen, with its quadrupled size, its muco-purulent infiltration, its enlarged tubes with blood or pus, would, we must grant, create as vivid a picture to the average mind as do those formidable cystic ovaries with catarrhal, serum, or pus-containing tubes of the feebler sex. Would the man be ridiculed or accounted behind the march of his peers who should venture the suggestion that that testis and its vessels would regain its integrity if treated conservatively, if allowed to stay in the body subject to nature's restorative forces?

The other special influence which damages the operator and his patients is the rage for "statistics." When a surgeon once gets the "record" fever his brain is excited by something less than science and much less than wisdom. Take for example a given case. An operator is rapidly

swelling his list of "successful cases of laparotomy"—his first fifty or his first hundred may be almost but not quite complete. A case of violent dysmenorrhœa, "ovarian neuralgia," or other neurosis presents itself. Think you he—or, indeed, the expert of the gentler sex—will risk the uncertainties and tediousness of general or conservative local treatment? Not for a week! The historical verdict reads: "An operation was immediately proposed and consented to. Operation performed May, 188–. Right tube catarrhal, both ovaries slightly cystic. Removed. Temperature never rose above 99° F. Recovery uninterrupted." Behold! the fifty, the hundred cases are now on record, and "a year's record in laparotomy" is brilliantly completed!

Are we drawing the picture too coarsely—are we weakening our argument by erratic hyperbole or by exaggeration? We ask you to read in the public medicine journals for yourself and see if such records may not be found.

This latter element I consider a most dangerous one to enter into the judgment of a surgeon's duty. It is to expect too much of human nature to suppose that we will not be biassed in our judgment by a desire to enlarge our list of brilliant deeds when numbers of operations become an incentive to emulation.

We have had so many reports, both verbal and in print, of these cases of late that it is only necessary to refer to one or two which represent fairly the work which this paper is in part intended to criticise. Within the past year we have been regaled by the report of one hundred and forty-four successful cases of abdominal section in a small West Virginia town within less than two years. Unless the operator had already become a veritable celebrity throughout that section of the country it would need no comment further than to denounce a course which must have been radical to a dangerous degree to have enabled him to have found it necessary to mutilate so vast a proportion of his unfortunate patients. But for fear that injustice may be done, and that this operator may have so vast a field as to make the proportion of abdominal sections to his gynecological practice much less than it seems to be, let us take a sample or two from his published records and consider their merits.

Case XI.—"Mrs. M. D——, married ten years; aged thirty-nine. Aborted two years after marriage, and states she was never well after this accident. Menses always lasted eight or nine days, and were so profuse that she was compelled to remain in bed for a week at least, after their cessation, to recuperate from the resulting exhaustion. Operation November 7, 1887, assisted by Drs. Thomas and Zerkle. Found both tubes occluded and adherent. Ovaries cystic."

"Case XVI.—Mrs. F. W. C——, aged thirty-six. Mother of two children. Two years since birth of last child, from which time illness dates. Severe menstrual pain. Locomotion difficult. Functional disturbances of the nervous system very prominent. Bilateral laceration of the cervix uteri. Both ovaries tender to the touch. Diffused pain and soreness over lower portion of abdomen. Operated on cervix April 14th, and on May 8, 1888, removed both ovaries and tubes. Left ovary contained half ounce of serum. Right ovary filled with blood and serum. Patient made rapid recovery."

"Case XIX.—Mrs. R. A. U——, aged twenty. Married nine months. Always suffered from more or less dysmenorrhœa and leucorrhœa. Constant uneasiness over the ovarian regions. Operation July 3, 1888, assisted by Dr. Thomas. Ovaries cystic and considerably enlarged. Tubes in a catarrhal condition."

"Case XX.—Mrs. M. A. L——, aged thirty-two. Always suffered more or less from dysmenorrhœa. Mother of two children. Dates her illness from an abortion two years ago. Pain of a 'dragging' character, nearly constant, over both ovaries. Uterus found to be immovably fixed in a retroverted position. Tubes enlarged and ovaries prolapsed. Operation July 3, 1888. Ovaries and tubes removed. Ovaries cystic and tubes distended with serum and slightly adherent."

"Case XXII.—Mrs. Julia M——, aged thirty; mother of three children. Suffers from severe pains in both iliac regions. Nutrition badly impaired. Uterus displaced backward and fixed. Operation July 7, 1888. Both ovaries cystic and tubes distended by serum."

"Case XXIII.—Mrs. C. E. W——, aged twenty-seven; mother of two children. Has been an invalid for two years. Great suffering from dysmenorrhœa. Found both ovaries enlarged and very sensitive to touch. Operation July 10, 1888."

"Case XXV.—Miss A. O——, aged twenty-three. Has been an invalid for several years. Severe dysmenorrhœa, and intense pain in back. Operation September 4, 1888. Both ovaries enlarged and cystic."

"Case XXVII.—Miss D. R. T——, aged twenty-three. Menstrual period lasts ten days. Has never suffered any pain, but the flow is profuse and the resulting exhaustion so great that she is obliged to remain in bed the greater part of every month. Operation September 6, 1888. Found both ovaries greatly enlarged, very soft and spongy."

These cases are sufficient to show that in one portion of our country, at least, abdominal section is resorted to with reckless frequency. What man is able to say that one of these cases would have resisted all other faithful treatment? If such cases require laparotomy, then at least four-fifths of our female patients are fit subjects for castration. But these instances only stand to represent the work of great numbers of operators, in city and country, who are endeavoring, apparently, to simplify their rules of practice by condemning the majority of troublesome cases to abdominal section.

Our scientific discussions are rendered tediously monotonous, if not ridiculous, by the rapid drift of debate into the delectable field of laparotomy and "tube" lore. But some man will say, all of this, or most of this moralizing is superfluous, for we believe all of this, or most of it, but it is a picture drawn from an extreme view of the practice of gynecologists. It does not fairly represent the facts as they concern the truly skilful man, but applies rather to those untempered imitators of men who are more fully qualified to judge when these operations to which we have referred should be performed. To this let us say, this paper ventures to remind the teachers in this department that to their one-sided radical way of dealing with a great proportion of pelvic diseases we may point as the guiding principle in the minds of the lesser lights of the profession. We will go further and aver that the teachers—the leaders themselves—so frequently assert their extreme dogmas that at length they believe thoroughly in them themselves, and put into practice theories which were in their minds once only theories, and doubtful ones at that.

In obstetrics, perhaps to a less degree, there exists the same spirit of non-conservatism. Many obstetricians seem more absorbed in the questions of the relative value of a Porro operation and a Cæsarean section than they do in the consideration of the best means to avoid the necessity for any such procedure.

It is safe to say that there are hundreds of women marred and many killed every year because of the lack of a reasonable amount of skill being shown to detect a malposition of the fœtal head. Thousands of dangerous forceps operations are done by men incapable of making approximate diagnoses.

Version is only resorted to after tissues have been lacerated and bruised by long forceps in the hands of several equally dangerous men. And then, if perchance it is discovered that a uterus is ruptured and two lives have been lost, version is ignorantly accused of having done the frightful deed. I have known at least two cases of craniotomy and one of Cæsarean section in multiparæ who had previously borne large children normally, and these formidable operations were done because a true conservative treatment had been ignored.

In our obstetric societies in this day how much discussion do we hear of the numerous forms of dystocia outside of those cases in which abdominal section may play a part? Are we not drifting away from good doctrines in our enthusiasm for surgical feats of uncommon skill?

Having thus in a somewhat cursory manner found fault with a strong indication of recklessness in our ranks, let us simply assert that a vast number of cases of pelvic disease would be conducted to a safe termination in cure, by a patient application of reasonable conservative treatment, which are being given up to the laparotomist's knife.

Enlarged tubes, if not enlarged ovaries, *will* resolve and empty themselves of serum, blood, and even pus. "Cystic ovaries" which contain cysts only of the Graafian follicular variety *will* continue to perform a healthy function if allowed to live.

Pelvic inflammations will disappear in a large number of cases without the knife applied through the peritoneum. Tender ovaries, adherent uteri, will regain their physiological functions in many instances, and childbearing will be possible in cases that are all too commonly condemned to mutilation. These and many other most important facts should be so firmly impressed upon our minds that we may be able not only to give our patients a fair opportunity to escape a dreadful mutilation, but also to discuss with candor the value of other modes of treatment which may suggest themselves.

To the inexperienced it is our bounden duty to sound a note of warning—to first learn to diagnose and treat the conditions of disease in the pelvis of woman in a thorough, scientific, and patient manner before he presumes to pass judgment on organs with which he has so slight acquaintance.

To show by a single example the baneful force of a one-sided view of surgical matters of vital importance, we have only to refer to a recent meeting of eminent obstetricians and gynecologists from various nations assembled in this hall. The subject of extra-uterine pregnancy was under discussion, and Professor Martin, of Berlin, whose opinions are justly held in high estimation, asserted that it was his universal practice to perform laparotomy in every case; and notwithstanding the unparalleled records of the American method of treatment by electricity, not a voice of dissent was raised, I believe, in all that assembly. Certainly no adequate rebuke to such a wholesale dismissal of our claims for electricity was offered. And who can tell the far-reaching influence of such teaching? Shortly after, a "primary operation" case of extra-uterine pregnancy was presented by one of our number, and with loud denunciations he spurned as triflers and ignoramuses those who presumed to claim that electricity ought to have even a trial on its merits.

A few cases may be of service in illustrating the changes that may occur in some of the conditions we have touched upon, and they have been selected from a long list extending over a period of ten years.

Case I. *Cystic Ovary.*—Mrs. V——, aged twenty-six, nullipara, had been married two years, never pregnant. Suffered several years with severe dysmenorrhœa, sacralgia, headaches, etc., with fixed pains occasionally in left groin. Was treated by a female gynecologist for several months; and at a consultation with an eminent practitioner in that department it was decided that a displaced, enlarged, and tender left ovary should be removed by laparotomy. There was also a retroflexed uterus without adhesions. The patient refused to submit to operation and was subsequently examined by me. I found the conditions above described, and put her through a course of tamponing with boric glycerine for six months, the applications being made once or twice a week in the intermenstrual periods. Afterward a good-sized Albert Smith pessary was tolerated and the patient became pregnant, went to full term, and was delivered of a healthy child. Three months afterward I examined her, and found the ovary as large as ever, not so tender, but in the same low posterior position. She has never had any symptoms of discomfort, even, since.

Case II. *Pyosalpinx.*—Mrs. R——, aged twenty-five, 1-para, no miscarriage. Had excellent health until after birth of her child, which was seven months old. She had slow convalescence from a tedious labor, being unable to get about without great pain for four or five weeks after confinement. She is said to have had continuous fever during that time. When she did get up she had great pain in the back, severe dragging pains in the groins, and a purulent vaginal discharge.

When she came to me the uterus was still enlarged and sharply retroflexed, and exceedingly tender. On each side of the uterus could be felt the outlines, distinctly marked, of sausage-shaped fluctuating tumors which were very tender. These were continuous with bands of adhesion binding the uterus in its vicious position in the hollow of the sacrum.

Notifying the patient that she should hold herself in readiness to submit to a serious operation if symptoms increased, I very cautiously instituted a very mild course of galvanism, followed by the glycerine and iodine tampons. From the cervix there flowed a stream of pus. After six weeks of patient work the tubes emptied themselves, the adhesions became less tender, and allowed the uterus to be partly reposited. At this time, seven months after the suspension of treatment, the patient reports herself as "perfectly well," and her appearance justifies the statement.

Case III. *Pyosalpinx.*—Mrs. H. S——, aged twenty-eight, 2-para, no miscarriage. Last child five months old. Delivered with instruments. Perinæum badly lacerated. Had bad getting up after both confinements, the last leaving her extremely weak and unable to walk without agony. Did not nurse the child. She was sent to me from a distant city and I placed her in my private hospital for treatment. She was just finishing a painless or almost painless menstruation when she was seized with rigors, rapid elevation of temperature—104.5° F.—and great pain in the right groin and hypogastric region.

Examination showed a perinæum torn to the rectal sphincter and with jagged, suppurating edges, the vaginal wounds being deep and pouring out pus. The cervix was torn slightly, but a stream of greenish-brown pus poured from the cavity of the uterus, which was fixed by adhesions in a retroflexed position. The whole vaginal vault was exquisitely sensitive, and the region of the right broad ligament, and posteriorly to the right of the uterus, was a large distinct mass which was exceedingly painful. For some days the patient's life was despaired of, so severely prostrated was she. I was urged by eminent counsel to operate later on for the removal of the tubes and ovaries, but owing to the patient's dread and my own doubts as to the absolute necessity of the operation the case was simply treated with iodine, hot douching later, and general tonic regimen. Within two months—a normal menstrual period having passed without disaster, and the pelvic roof showing improvement—she was etherized and the perinæum repaired. Her recovery was good, and at my request she has presented herself for examination within a few days past.

In reply to my questions she states that her health is "better than it has been in five years," that she has positively no pain nor tenderness. On examining the pelvic organs I find the uterus partly retroflexed and partly fixed, the tubal swelling and other evidences of exudation are entirely obliterated, except a suspicion of a tense cord in the position of the pyosalpinx diagnosticated six months ago.

Case IV. *Ruptured Uterus.*—This was a case of rupture of the uterus, occurring during the second stage of normal labor, and has been reported in full in a previous paper. I only allude to it here to show that the treatment was rationally conservative, and saved the patient, whereas laparotomy is recommended in such cases without question. This woman had a rupture of the uterus at its right

anterior upper segment, which allowed the body, legs, and one arm of the child to escape from the cavity of the uterus. All of the symptoms of the catastrophe were present. I introduced a clean hand, and drew the escaping child into the uterine cavity again, and turning it, delivered rapidly. The placenta and membranes being carefully removed, I examined the fœtal envelopes and found *but one opening*—that through which the child was delivered—namely, the vaginal portion. At once recognizing the evidence that the membranes above had formed a hernial sac ahead of the child as it had been thrust through the rent in the uterine muscle, I felt sure the peritoneum had no amniotic nor other fœtal substances poured into it, and determined to give the case to nature to absorb the clean blood which had escaped into the broad ligament and elsewhere, to the amount of a pint. The patient recovered entirely, and I delivered her by version within two years after the above related accident.

Case V. *Pelvic Peritonitis; Ovaritis; Pyosalpinx* (?); *Subsequent Pregnancy.*—This case may be related in a few words which will carry a forcible lesson. Mrs. L——, aged twenty-four, nullipara; good history. Shortly after marriage she was taken sick with what she called "inflammation of the bowels," and after weeks of suffering in bed she so far recovered as to apply for relief of her pelvic pains and soreness at the office of a distinguished gynecologist of this city. He found her in a bad state, suffering from a recent attack of pelvic peritonitis, with an enlarged and exquisitely sensitive right Fallopian tube; and for some reason—I believe because she refused to permit laparotomy—he referred the case to me. On examining her I found the pelvis filled with exudation, the uterus fixed firmly in a retroflexed position, and the right ovary and tube enlarged and very tender. I could not detect any fluctuation. This case had been repeatedly inflamed until everything seemed massed together in one great cicatrix.

Guided by an experience with such cases, I put her through a most thorough course of douching with hot salt water, iodine and glycerine tampons, etc. In one year she became pregnant, and she was delivered, at term, by my assistant, Dr. Tracy, after an unusually easy labor. A good convalescence followed, and to-day the pelvis is free from evidences of exudate.

These, with a variety of other cases of every degree of severity, which I might weary you with, will serve to point the moral that there is something else to be done for the salvation of our cases than the grave operations which open the abdominal cavity. But I would feel that this paper had sadly miscarried should it be interpreted to teach that active interference is to be put aside in all cases. Let no man impute to the reader any uncertain sound, any cowardly inaction. There is a time to act, and then to act promptly and thoroughly. There is a time to stand by and guard the patient against mischievous meddling, to wait patiently for results which will come to the rescue; and in so doing it is as much to our credit as is the most intricate surgical achievement. A general surgeon may display uncommon skill in the use of the amputating-knife, but he is a better surgeon who knows when to withold the knife and save the mangled limb.

He who is gifted with a skill to invade the great cavity of the body, with dexterous fingers to detach and remove offending tissues, is to be looked upon with reverence if he abuse not his art. But on him rests a fearful responsibility which he must ever bear—a responsibility to his patients, and to those, in less degree perhaps, of every practitioner who sees his skill or who reads of it in the journals of our profession. Let him see to it, then, that no sordid motive urge him to advocate or put into practice an operation which is not demanded by the best interests of his patient. And on the other hand, let no man stand, through bigotry or ignorance, in the way of prompt and efficient measures, no matter what they be, so long as they be right and just, and in demand. Conservatism is not cowardice, is not clumsy inaction, any more than it is reckless impetuosity.

Would it not be better for our post-graduate schools, our scientific societies, and our representative gynecologists, to lay greater stress on the skilled use of the instruments demanded in minor surgical gynecology; on the proper observation of the general rules of treatment, of antiseptic details, and of careful diagnosis, than to fill the minds of the growing brethren in the profession with ideas which tend to a strong bias in favor of a dangerous and often harmful operation.

How many men are expert in the details of a thorough pelvic examination? How many are there who are strictly guarded as regards septic infection of their patients? If it can be shown that the vast majority are well-trained, conscientious workers in these commonplace details, then will we admit that they are ready to receive their first lessons in abdominal surgery. But the experience of men who are brought in contact with these special cases frequently goes to show that there are men who will rise up in our societies and argue for the inevitable demands of laparotomy, etc., whose awkwardness in the use of the Sims speculum even would be apparent to all of us.

As a sign of the times I would like to relate the experience of a gynecologist to one of our hospitals within the past year. He had succeeded, in the rotation of service, a gentleman of growing reputation as a laparotomist, and found the service pretty well given up to cases of abdominal section. His attempt to awaken the interest of the House Staff in the minor operations, perineorrhaphy, trachelorrhaphy, in cystic inflammations and the like, was a signal failure, the staff to a man being utterly indifferent to anything less than an extirpated ovary or tube. And yet there was not a man on that staff possessed of the requisite amount of skill to introduce, without pain to the patient, an ordinary speculum! Further comment is unnecessary.

The rational use of antiseptics in all departments of surgery have brought improvements which mark an era in our art; but this extension of our work has also brought its evils.

Depending upon the protection given by clean surgery we are emboldened to invade tissues with too much recklessness, and without sufficient warrant or deliberation. Furthermore, it is well to bear in mind that a cure, or even the improvement of a symptom, does not always follow what is often designated as a successful operation. A patient may, indeed, escape the immediate dangers of the operation, but very often—more often than operators are willing to make note of—she is left in a state which is worse than the first.

If the cases of abdominal section were fairly reported upon one or two years after the successful operation we might be less sanguine in following the example of the great surgeon of Birmingham.

Ventral herniæ, extensive and painful peritoneal adhesions, fistulæ, and a suspicious increase of melancholia, these are some of the fruits of laparotomies which have been previously reported among the hundreds of successful cases. But is there no field for this important surgical exploit? Is laparotomy only the hobby of enthusiasts? Certainly there is a field for this very successful branch of surgery, but we wish it distinctly to be understood that its field of real usefulness is *limited*, and within its proper limitation it is the only proper course to pursue.

To push its application outside that limitation is to abuse it, and to distort the clear judgment necessary for a just consideration for the patient's welfare.

---

Dr. Prince A. Morrow, of this city, is engaged in collecting statistics of all cases of leprosy in this city, and asks medical men to send him reports of any case or cases under their observation.

## BASILAR KYPHOSIS: ITS RELATIONS TO CERTAIN CEREBRAL DEFORMITIES.

By SARAH E. POST, M.D.,
NEW YORK.

By basilar kyphosis is meant a deformity of the skull homologous with kyphosis in the spine.

Spinal kyphosis consists in an altered position of the vertebræ, producing a dorsad angle in the place of a curve. The angle of spinal kyphosis is formed by the spinous process of the vertebra most prominent in its outline. If, however, we should strip the offending vertebræ of all their processes, if we should even remove the neural arches altogether, we would still find the angle represented by the bodies of the vertebræ; we would, in fact, have it borne in upon our minds that the angle was primarily induced by malposition of these bodies, being merely accentuated by the neural arch and the process carried upon it.

Such a resolution of the grosser appearances of kyphosis is provided by nature in the configuration of the skull. Here we have three primitive vertebræ (Virchow), the bodies of which are represented by the base of the skull or os tribasilaire, composed of the basilar process of the occipital bone, the post-sphenoid, and the pre-sphenoid bones, the neural arches being represented by the cranial vault. Here there is no prominent spinous process to attract attention to the deformity. The laminæ, too, fail to follow the displacement and to indicate its presence in any as yet significant way. We say, as yet, because it is probable that upon further study the vault of the cranium will be found highly significant in these cases.

In basilar kyphosis, then, we have a dorsad or posterior angle, which is to be found in the bodies of the constituent vertebræ, or the base of the skull. Ossification between the two sphenoid bones is well advanced at birth, so that the two already form one compact mass known as the body of the sphenoid. Ossification between the occipital and sphenoid bones is, on the contrary, not completed normally until the eighteenth or twentieth year. Following the principle that the part last developed is that most apt to be malformed, the angle of basilar kyphosis will be found primarily to include the occipito-sphenoidal articulation, the post-sphenoid bone representing the malformed vertebra, the clavicular process being its most prominent point.

In addition to the essential angle of basilar kyphosis, we find two contiguous angles which are important in assisting to describe the topography of the inner surface of the skull. Cephalad, or at its upper border, we find the angle which the body of the sphenoid makes with the deepest level of the anterior cerebral fossa; and caudad, or at its lower border, the angle which the basilar process makes with the level of the occipital foramen. The latter angle is determined by the articulation between the primitive pedicles and laminæ of the occipital bone, the line of which passes through the occipital condyles and the condyloid foramina. This angle is normally diminished in the fœtal state, giving rise to the steeply inclined basis cranii and the globular skull of the fœtus, in which absence of depth in the anterior and posterior cerebral fossæ are apparently more characteristic than occipito-sphenoidal kyphosis, or infringement upon its median vertical diameter.

Basilar kyphosis is not simply a persistent fœtal trait, it is a distinctly abnormal or pathological condition.

The angle of basilar kyphosis is an exaggeration of the normal angle made by the basilar process of the occipital bone with the body of the sphenoid, its projection being into the cavity of the skull. It is apparent that basilar kyphosis markedly diminishes the intra-cranial capacity, it is apparent that the angle of basilar kyphosis encroaches upon the cavity of the skull, first by shortening its cephalo-caudad or antero-posterior diameter, and second, by direct infringement upon its dorso-ventrad or vertical diameter. The distance between the base of the skull and its roof is diminished in basilar kyphosis beyond the proportion necessitated by its contracted antero-posterior limits. The importance of the deformity in its effects upon the brain may be readily appreciated.

Th. Ackermann [1] has found basilar kyphosis in a number of cases of encephalocele, the result being fairly uniform whether there were anterior or posterior cranial defect. Ackermann considers the kyphosis a result of diminished intra-cranial pressure consequent upon the defect.

Now, this is an interesting point. From the earliest historic times encephalocele has been well recognized, yet up to the present day the question of priority continues to be propounded. Did the cranial defect exist first, and did the brain take its erratic growth as a result of the loss of its enveloping wall; or did the hyperplasia or the hydrocephalus exist first, compelling non-union or loss of substance in the yielding cranial bones? If, as Ackermann surmises, hydrocephalic processes leave their impression upon the base of the skull, we may interrogate this part in the investigation of a number of doubtful conditions. If basilar kyphosis is inconsistent with increased intra-cranial pressure, the loss of cranial substance was not produced by pressure in these cases of encephalocele, but was what, for want of a more intelligent term, we designate as a primitive defect. The experiments of Dareste, Lebedev's study of the chick's embryo, and William Koch's exhaustive study of spina bifida, also sustain the opinion that bony defects at least do not depend necessarily upon hydrocephaloid conditions. Koch, quoting Ranke's theory, considers the bony defect in both myelocele and encephalocele alike due to failure of separation between the cutaneous and medullary layers after the formation of the medullary canal. On account of this failure a septum continues to unite the neural tube with the skin, and effectually prevents union between the osseous and muscular layers. These finally, by increasing in thickness on all sides

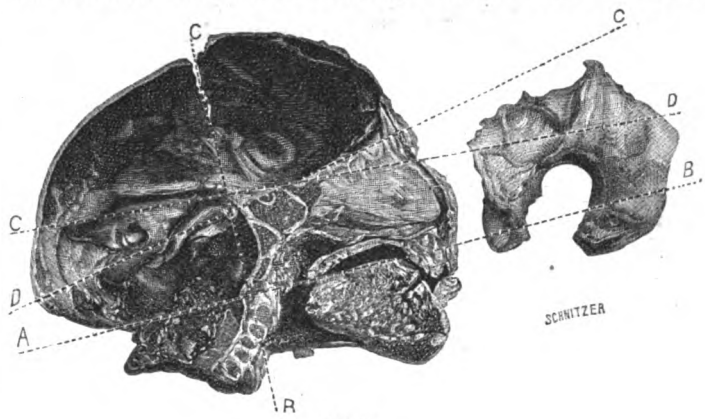

FIG. 1.

[1] Th. Ackermann: Die Schädeldifformität bei der Encephalocele Congenita. Halle, 1882. Ackermann's method of measuring basilar kyphosis is to make first a median vertical section of the skull, and upon this section to construct lines, the first to pass antero-posteriorly through the centre of the section of the basilar process, and the second antero-posteriorly through the centre of the compound body of the sphenoid, the inequalities of the surfaces being disregarded in the measurements. The resulting angle is termed the occipito-sphenoidal angle, or the angle of the saddle, found to consist normally of one hundred and fifty-seven degrees. The angle may be easily constructed in a normal skull, but in a kyphotic skull instruments of precision would be required, and even then the surface inequalities with which alone the brain has to do would not be adequately represented. We have therefore preferred a surface measurement such as may be made by anyone without trouble.

Of the four lines used to represent the base of the skull in this paper, all occupy the median vertical plane: *AB* passes through the level of the occipital foramen; *BC*, from the inner ventrad margin of the occipital foramen to the apex of the clavicular process or most prominent point of the post-sphenoid bone; *CD*, from the apex of the clavicular process to the apex of the olivary process or most prominent point of the præsphenoid bone; and *DE*, from the apex of the olivary process to the level of the cribriform plate, this being approximately a measure of the depth of the anterior fossa. The lines *BC* and *CD* represent the occipito-sphenoidal angle or the angle of basilar kyphosis.

of the septum, exert traction upon the neural organ and elevate it from its bed in the canal. Increase in weight, gravity, and subsequent meningeal effusion, complete the work thus begun. It is well known that encephalocele and myelocele are apt to be umbilicated or furrowed.

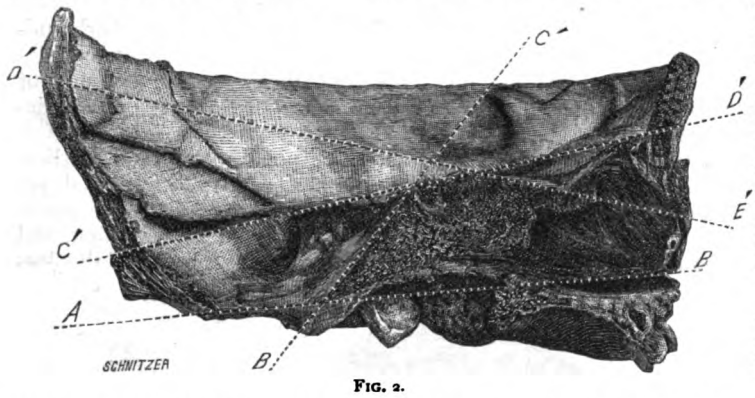

FIG. 2.

The place of umbilication or furrowing is supposed to locate the primitive defect. Koch considers the shortening of the spinal column, the absence of certain vertebræ, and the dwarfing of others in pronounced cases of rachischisis, also the existence of rachischisis without neural involvement, as all opposed to the theory of hydrocephaloid origin. Koch considers that encephalocele may become hydrencephalocele by loosening of the band of connection between the neural tube and the skin, and the partial sinking back of the hernia into the canal.

We are fortunately able to present in this connection a typical skull illustrating Ackermann's cases. The drawing shown in Fig. 1 has been made from a photogragh of this skull, and is in all respects quite accurate. The case was one of hydrencephalocele, reported by Dr. McNutt before the Clinical Society of the Postgraduate Medical School, April 16, 1887.[1] The patient was a male child, born at term; the delivery was normal. The parents were young, healthy people, but emigrants, and the mother had, during her pregnancy, suffered many hardships, including deprivation of proper food. The tumor was present at birth. It was located in the occipital region, was translucent, and toward the base covered with hair. The bony defect occupied the median line of the occipital bone, the bones of the skull were soft, the fontanelles

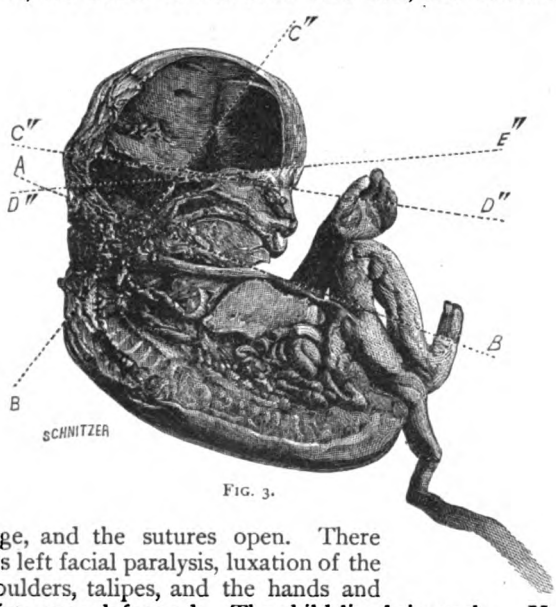

FIG. 3.

large, and the sutures open. There was left facial paralysis, luxation of the shoulders, talipes, and the hands and wrists were deformed. The child lived six weeks. Upon autopsy the sack of the tumor was found to consist of the dilated fourth ventricle, the cerebellum was absent, the occipital convolutions interlocked, and the pedicle of the tumor contained degenerated cerebral tissue.

[1] The Postgraduate, January, 1888, p. 55.

Sutton ascribes the tumor of occipital meningocele to closure of the canals connecting the lateral recesses of the fourth ventricle with the subarachnoid space. The tumor is the dilated fourth ventricle. It is associated with a rudimentary or absent cerebellum, if developed at an early stage of intra-uterine life. The theory of Sutton would produce hydrencephalocele by distention of the central canal and the mechanical withdrawal of cerebral tissue, the agent being the traction exerted by the growing tumor upon the adjacent cerebral mass. This is the old theory of hydrocephalus, pressure and defect, opposed to which we have the theories of Ackermann and Koch, to which we have already referred. The evidence afforded by the skull in Dr. McNutt's case is before you.

Fig. 2 is a drawing made from a photograph of a normal skull, taken from a child of one year. It is presented simply for purposes of comparison.

Fig. 3 is a drawing made from the photograph of a skull of a fœtus of about four months. It is also given for comparison only. The angles made by the inner surface of the base of the skull in these three cases are compared in Fig. 4. Bearing in mind that the lines used to represent this schematic diagram are of precisely the same length in the three cases, the infringement of the cavity in both the fœtal and kyphotic skull will be found

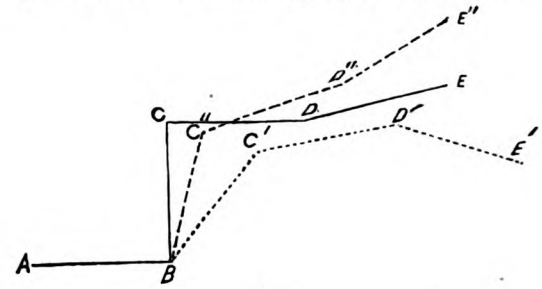

FIG. 4

there graphically represented. It will be readily seen that the occipito-sphenoidal angle is very nearly the same in the fœtal and in the post-natal normal skull; but, that the capacity of the fœtal skull is proportionately diminished by the tilting of the whole base upward on the axis furnished by the articulation in the lateral masses of the occipital bone; and still further encroached upon by the upward inclination of the anterior cerebral fossa. The result of these two forces is to shorten the base and diminish the capacity of the skull. In the kyphotic skull this result is exaggerated by sharpening of the occipito-sphenoidal angle. The base of the skull is here comparatively still shorter and the cavity more contracted than in the fœtal condition. In the kyphotic skull we have persistence of the fœtal peculiarities, and, added to these, occipito-sphenoidal kyphosis.

Basilar kyphosis has been associated in cretins with premature synostosis (Virchow) of the base of the skull, and it has been in some treatises ascribed to persistence of a normal fœtal condition made permanent by this means. So far as isolated examples can carry weight, these specimens would appear to negative such a proposition. In the first place the fœtal skull here represented does not show basilar kyphosis, and in the second place the kyphotic skull does not present synostosis. We have noted that the bones were soft, the foramina large, and the sutures open. Even the intersphenoidal articulation is still cartilaginous. The same was true of all of Ackermann's cases.

A second point of interest connected with basilar kyphosis has to do with the symmetric bilateral atrophy of the brain found in cases of infantile spastic biplegia. By post-mortem examination Richter[1] has found basilar

[1] Richter: Virchow's Archives, No. 106, p. 390.

kyphosis in a number of cases of this kind. His observations were made by dividing the head vertically in the median line while the brain was *in situ*, and he graphically describes his finding. He viewed the brain curved around and carried up by the kyphotic prominence. As a result he saw collision of the falx with the corpus callosum in the median line, producing atrophy of the callosum, the degeneration proceeding centrifugally to the cortex upon both sides.

This explanation must be eminently satisfactory to anyone who has puzzled over the various theories offered for these symmetric cases of corticalatrophy. It is not, however, quite unobjectionable. The corpus callosum does not in the adult undergo secondary degeneration. The cortex atrophied by embolus will be represented by secondary degeneration in the tracts to the periphery, but no line of secondary degeneration crosses from it to the opposite side of the brain, as in infantile biplegia, where, as in Dr. McNutt's case,[1] an atrophied band in the callosum connects the atrophied convolutions.

Again, we know that the corpus callosum is not essential to the building of convolutions.[2] An Englishman has recently collected thirty-three cases of absent corpus callosum in otherwise fairly formed brains. His own case lived to manhood and was reasonably intelligent, attending to his business, and only considered a little stubborn and queer by his friends. Why cutting the callosum during fœtal life should inhibit the growth of convolutions is yet undetermined.

A further point of interest is found in a case of biplegia in which Richter demonstrated basilar kyphosis, but in which the paralytic seizure dated from the sixth year. Of sixteen cases of biplegia reported by Osler, ten only were congenital. Must basilar kyphosis be fœtal in origin, or may it, like spinal kyphosis, have its inception later in life? Richter's explanation of this post-natal case is that the deformity had previously existed, but had not interfered with the brain until its later development.

To enumerate:

1. The essential feature of basilar kyphosis is sharpening of the occipito-sphenoidal angle. It is associated with a steeply inclined basilar process and superficiality of the anterior cerebral fossæ—characteristic fœtal conditions.

2. The direct effect of basilar kyphosis is to shorten the base and to diminish all of the diameters of the skull.

3. Basilar kyphosis is not necessarily associated with premature synostosis of the base of the skull.

4. Basilar kyphosis has been found in cases of congenital cerebral hernia. In this connection it is supposed to exclude intra-cranial pressure as the cause of the cranial defect.

5. Basilar kyphosis has been associated with the symmetric cortical atrophy of infantile biplegia. It is supposed to cause this condition by bringing the corpus callosum into collision with the falx cerebri and inducing inhibition or atrophy proceeding centrifugally to the cortex upon both sides.

The mother's deprivation of food during her pregnancy, together with the delayed ossification, may not inappropriately suggest intra-uterine rachitis as a cause of this deformity. In the case of biplegia to which reference has been made, the ordinary signs of rachitis were very evident. Rachitis as a basis for biplegia may not impossibly repay investigation.

In concluding, I beg to express my indebtedness to Dr. Sarah McNutt for the opportunity of studying her specimens, also for many other kindnesses which have greatly forwarded my work.

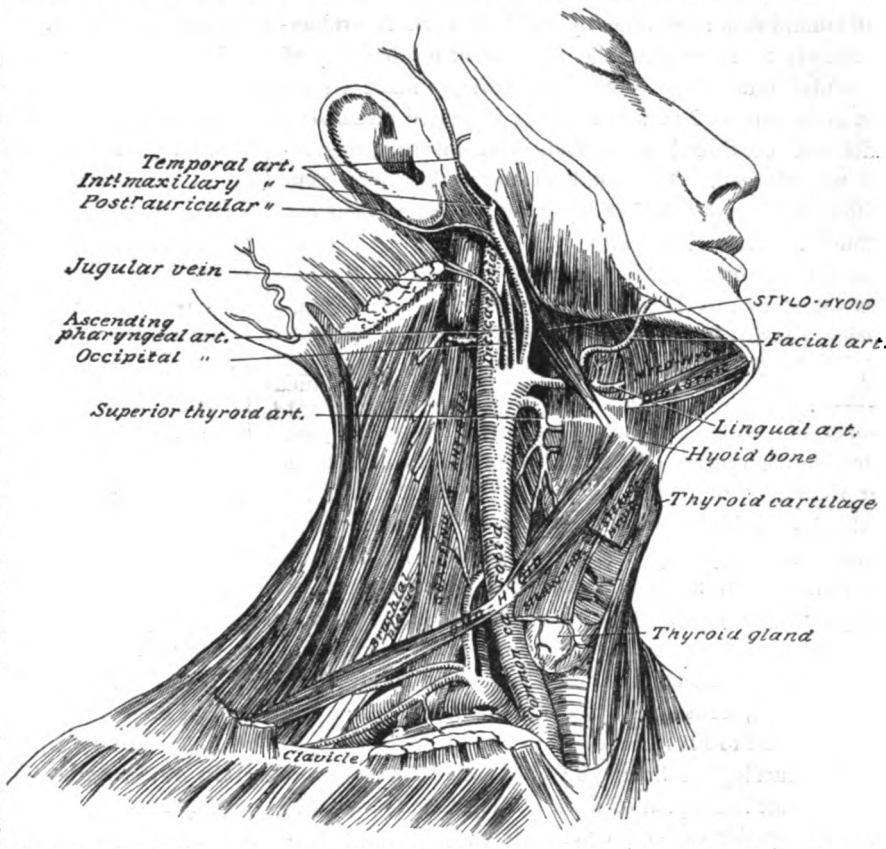
## AN ANOMALOUS RIGHT EXTERNAL CAROTID.

By J. HARTLEY ANDERSON, M.D.,

PITTSBURG, PA.

In a recent dissection I found at the bifurcation of the common carotid, which took place opposite the greater cornu of the hyoid bone, and immediately below the posterior belly of the digastric, an axis of five vessels, corresponding to the branches of the external carotid.

The first branch was the superior thyroid, which ran down to the thyroid cartilage, giving off its usual branches. The second branch corresponded to the lingual, which gave off the facial about a third of an inch from the axis. The third branch was the inferior maxillary, giving off the posterior auricular and the temporal, both of which were small. The fourth branch was the occipital. The fifth, the ascending pharyngeal, arising from the underneath part of the axis. The branches of all the arteries, except the cervical branches of the facial, were normal in position. The internal maxillary was small in size, as also was the occipital. In ligating on this artery the operator may expect to find all kinds of anomalies. The origin of the external carotid may usually be found opposite the superior border of the thyroid cartilage, but very often it is found as high up as the hyoid bone, and as low as the cricoid cartilage. Morgagni cites a case in which the origin was an inch and a half above the subclavian. There are on record two cases in which the origin was on the arch of the aorta. In one case this anomaly was on both sides, and on one side in the other. As I have nowhere seen a description of this axial arrangement, I thought it might be of some use to bring it to notice. Dr. Quain mentions an arrangement of the vessels in close proximity, on the external carotid, from which I infer that it was not axial.



THE MEDICAL RECORD:

## EPILEPSY, CHOREA, AND THE EYE MUSCLES.

THE commission appointed by the New York Neurological Society to investigate the relation of insufficiency of the ocular muscles to chorea and epilepsy made its report in November last, and after an animated discussion, which was continued at the December meeting, this report was adopted. The details of the work of the commission will be published soon, and it will be a document of much interest. Meanwhile, we shall give our readers some account of this work from the records of the Society's sessions that have been furnished us. The Commission consisted of Drs. E. C. Seguin, William R. Birdsall, F. P. Foster, Charles L. Dana, M. A. Starr, D. Webster, and W. O. Moore. These gentlemen worked in co-operation with Dr. George T. Stevens for the purpose of testing the validity of the latter gentleman's statements that treatment of insufficiencies of the ocular muscles would cure a large percentage of cases of epilepsy and chorea. In a paper by Dr. Stevens, published a few years ago, it had been asserted that about fifty per cent. of epileptics were relieved of their attacks by the special form of treatment referred to. Dr. Stevens has since then obtained some confident and aggressive followers in this city, and, consequently, considerable attention has been attracted to his method.

The Neurological Society's Commission, according to the statement in its plan of work, having found a suitable case of idiopathic epilepsy or chronic chorea, had the patient examined separately by two of its neurological members and a full history taken. The patient was then sent to Dr. Stevens and examined by that gentleman. If acceptable, further eye examinations were made again by one of the ophthalmologists of the commission. Each patient, therefore, went through four separate examinations before treatment was begun. Records were then kept of operations performed and of the progress of the case.

Twenty-eight patients were thus examined and put under treatment, but for various reasons fourteen were withdrawn, or not counted. In some cases the patient could not follow up treatment; in others, no relief being obtained, they refused to attend; in others, some evidence of organic disease developed. Several attended less than the minimum limit of time adopted as a test of treatment, viz., four months. Fourteen cases, however, were treated continuously for over four months, and in some instances over two years. Nine of these cases were of epilepsy; five of chronic chorea. Three of the cases of epilepsy and three of the cases of chorea were improved. None were entirely and completely cured, although two of the cases of chorea seem to have become practically well. None of the cases of epilepsy were cured or even very strikingly improved, though as to this latter point there seems to be some difference of opinion.

The commission, in their conclusions, state that they cannot recommend a treatment of insufficiencies of the ocular muscles in cases of epilepsy and chorea as the sole therapeutic measure or as a curative measure. This conclusion does not deny to oculo-muscular treatment all value, but it is evident, from a perusal of the discussion, that the members do not attach very much importance to it. At the best, it seems that ocular irritation from muscular insufficiency may exaggerate or keep up a convulsive disorder; just as a tight prepuce or disordered stomach may do it.

The importance of peripheral irritation, however, as a cause of the severe neuroses, is no doubt vastly exaggerated; perhaps no more by oculists than by other specialists. There will continue to be a diversity of opinion as to the exact value of Stevens' oculo-muscular treatment. It will be impossible, however, for any candid person to read the commission's report and thereafter believe that this method is a specific for epilepsy, or that it is really a curative measure. In chronic chorea the results allow a wider divergence of opinion. But, although several cases were very greatly improved or even cured, this occurred only after a long time, and it might be attributed to the natural course of the disease.

Although the extravagance of Dr. Stevens' claims is abundantly shown by the commission's report, some words of justice are due him. It was certainly a courageous act on his part to undertake the somewhat thankless task of allowing his views to be put to so exacting a test, and it argues an honest conviction in the truth of his own views.

By his persistence and ingenuity in following up his special line of work attention has been drawn to a class of functional eye disturbances which had been very generally overlooked. The exact importance of these in the production of morbid symptoms and the pathogeny of disease time will determine definitely. It is already shown that their importance has been greatly overrated.

## VITAL AND MEDICAL STATISTICS.

THE lectures of Dr. Billings upon vital and medical statistics have proved to be of much more interest than their title promised, and they will doubtless serve a useful purpose in showing the proper methods of carrying out a statistical inquiry as well as the limitations of this method. The familiar observation to the effect that "one can prove anything by statistics is false," unless it is amended so as to say "by statistics ignorantly used."

Whatever may be the shortcomings of the statistical method it is the one which practically has to be largely used by the physician in order to draw conclusions as to the course of disease; and it is most desirable, therefore, that he should have an intelligent understanding of the tools which he has to employ.

Dr. Billings' lectures dealt not alone with statistical methods, but also with the application of them in many directions. He presents us, it must be confessed, a rather discouraging picture of the result of man's battle with disease. Although the expectation of life is greater, yet this is only true of the earlier ages. After a man reaches twenty his expectation of life is less than it was fifty years ago, for the reason that more persons of feeble constitution are now nursed to manhood.

The decrease in the general mortality is due to better care of infants and the prevention of contagious disease.

So far as statistics show, it does not appear that there is any difference in the mortality-rate of most infectious diseases from what it used to be. Pneumonia, diphtheria, scarlet fever, measles, small-pox are just as fatal as they used to be. Or if there is any difference, it is one which may be attributed to the special character of the epidemic, or the age and constitution of the people. Deaths from child-bed and surgical operations, it is true, are shown to have been greatly reduced.

We regret that the statistics of typhoid fever were not dealt with by Dr. Billings, because there is asserted to be a great reduction in the mortality from that disease by modern treatment.

When one comes to study death-rates and sick-rates of hospitals and among poorer classes he is confronted with a peculiar problem. Therapeutic measures efficient elsewhere do not apply here. A case of phthisis in the early stage dies or gets well exactly in accordance with modern treatment. This is a fact which physicians know, yet statistics would probably show just as great a mortality-rate from this disease as ever.

Every physician meets cases in which, by timely treatment, he has saved victims of scarlet fever, diphtheria, and pneumonia, etc., yet statistics do not show it, while, of course, mortality statistics do not tell of what is done in non-fatal disease or of the cured cases. So that, altogether, modern medicine no doubt accomplishes more than is apparent by figures and tables.

---

## WHOLESALE OFFICIAL PRESCRIBING.

We notice with considerable surprise the publication in the daily papers of a prescription for the threatened epidemic of influenza, which is said to be by the sanction of the Board of Health. We trust we have been misinformed on this subject, as the so-called remedy is not only of no good whatever, but its use as directed is liable to be attended with great danger. Here is the prescription in question:

"For Russian influenza or 'grip'—spray the affected membrane with a ten per cent. solution of quinine freely and frequently, and take four or five times a day a pill made as follows: Quinine, 3 grains; camphor, ½ grain; extract of belladonna, ¼ grain."

Very many of the pharmacists about town have very properly refused to make up the prescription, and very many patients who believe in wholesale cheap prescribing may follow the directions to their sorrow. We cannot believe that the publication of this prescription is made by the authority of the Health Board. If it is, the Board owes an explanation and apology to the profession and the public.

## THE HOMŒOPATHIC HOSPITAL AFFAIR.

During the past few days a very interesting quarrel has been agitating homœopathic circles regarding the real articles of faith upon which the Hahnemannian creed shall rest. The questions at issue have been precipitated by a protest, on the part of the Homœopathic Society of this county, against certain gentlemen who are not members of said society being retained upon the Medical Board of the Homœopathic Hospital at Ward's Island.

It will be recollected that fifteen years ago the Commissioners of Charities and Correction set apart the Ward's Island Hospital exclusively for homœopathic practice upon the patients, and appointed acknowledged homœopaths upon the Medical Board. It now appears that five of the twenty-four physicians constituting the board are not members of this society; are consequently not declared homœopaths, and that the society has passed a resolution petitioning the commissioners to dissolve the board and appoint a new set, who shall all be members of the society.

The following queries were also laid before the commissioners:

"1. Do the commissioners intend that the Medical Board of the hospital should be composed exclusively of homœopathic physicians? 2. What is their criterion of judging if a physician is homœopathic? 3. Is membership in the Homœopathic Medical Society of the county that criterion? 4. Is a physician who does not comply with the law of the State eligible? And, 5. Do the commissioners intend that a physician who has left the Homœopathic Medical Society shall continue a member of the board?"

These questions were referred to the President of the Medical Board, and he replied that he believed there was no exclusively homœopathic physician in New York; that the law requiring physicians to belong to a county society was a dead letter, and that the reasons why two members had left the County Society were more creditable to them than to the society.

It is claimed by the other side that the intention to follow homœopathic principles can only be made manifest by a membership in their Homœopathic county society.

During the discussion of the question *pro* and *con* many curious facts have been brought to public notice, which show a very uncertain state of conviction on the part of those who are within the circle. It is admitted by several, if not all, the parties in the quarrel that homœopathy is not faith in infinitesimals, or in so-called potentization by trituration, but is the "like cures like" principle. Even this latter, we are told, is not a universal truth or absolute guide. Consequently a modern homœopathist uses the latter principle as the best general guide in selecting remedies. This appears to be the minimum modern test for a homœopathist, since the members of the society can claim no more.

Whether the members are right or wrong in their belief does not concern us. Each one is free to believe as he pleases and practise such a belief according to his conscience and the faith of those who place their lives in his hands. It is eminently proper for such as have a creed to stick to it.

Happily for the regular profession, it can view the situation with absolute impartiality, as from the nature of

things no quarrel upon the points involved could ever occur among us. In the absence of any other authority for homœopathy than that assumed by the society, we do not see how the said society can do other than endeavor to purge the Homœopathic Hospital of those men who do not even follow this "like cures like" rule.

As a matter of principle, if the Homœopathic Hospital has been set apart exclusively for homœopathic practitioners by the county society, the medical staff of the hospital should be composed of men concerning whose belief in the original dogma there should be no question. There does not seem to be any way of avoiding the issue. There has always been acknowledged intimacy between faith and works, and they cannot be consistently separated in this instance, despite the apparent ambition of the society to secure patronage. We sympathize with the gentlemen who are bold enough to be independent in their conviction, but it is this very independence which should invite their resignation as men who cannot practise what they do not believe. Hence it must be conceded that the decided vote by the Society, at its meeting on Wednesday night, to petition the commissioners to reconstruct the board, was perfectly proper and eminently sound.

## News of the Week.

For Sick Babies.—Many well-known ladies attended the house-warming in the babies' ward at the New York Post-Graduate Hospital, Nos. 222 to 230 East Twentieth Street, Wednesday afternoon. Among the many charities of New York there has been almost no provision made for the care of sick infants. The general hospitals decline to receive them, and many babies die because their mothers are unable to give them suitable nourishment and medical treatment. Recognizing this fact, the directors of the Post-Graduate Hospital, assisted by several charitable ladies, established a babies' ward. The work grew so rapidly that it was found necessary to occupy an entire building, next to the hospital proper. During the past summer more than one hundred babies were treated. No cases except contagious diseases were refused. The babies' ward is under the medical care of Dr. Henry D. Chapin. Addresses were delivered by Dr. D. B. St. John Roosa, Dr. Chapin, and the Rev. Dr. Satterlee.

Fatal Superincumbrance.—The deaths of fourteen infants in London, in one week, were attributed to "overlaying." The cause of one death in this city, last year, was reported to be "Sat on by Father."

One-half per Cent. Solutions of Creolin are becoming popular for vaginal injections, for washing out the bladder, and as injections in dysentery.

Alumni of Charity Hospital.—At the meeting of the Medical Society of the Alumni of Charity Hospital, held on the evening of December 10th, Dr. A. T. Muzzy read a very interesting paper, entitled "The Prevention of Ophthalmia Neonatorum." Dr. Joseph O'Dwyer presented some new laryngeal tubes, which are shorter than his former models and of much larger calibre—in fact, giving a passage very little smaller than the trachea itself, thus facilitating the removal of membrane, mucus, etc. Another modification is having the collar at the top of the tube hinged to the shaft in front, so that removal is easily performed by the finger. The collar, which is held in place by springs, lifts up readily, forming a ring into which the tip of the finger is inserted and the tube readily withdrawn without the use of instruments. The following officers were elected: *President*—Dr. D. Bryson Delavan; *Vice-President*—Dr. Ramon Guitéras; *Secretary*—Dr. W. L. Baner; *Treasurer*—Dr. A. T. Muzzy.

Hydrotherapy vs. Hydropathy: A Correction by Dr. Baruch.—Dr. S. Baruch writes: I desire to ask the correction of an error which has crept into your valuable report of my paper, "A Plea for the Practical Utilization of Hydrotherapy." Your reporter refers constantly to *hydropathic* measures, *hydropathic* treatment, *hydropathy*. The following extract from the paper will furnish my reason for asking the correction. I said that "hydrotherapy is the utilization of water, at any temperature and in any form (from ice to vapor), internally or externally, for the treatment of disease. I do not say *the cure of disease*. By this definition we emancipate it from hydropathy, a cold-water cure, and place it in the front rank of therapeutic measures." It is my aim to draw the line distinctly between a therapeutic and a sectarian term, because the adoption of the latter (hydropathy) by empirics has long estranged the profession from the use of a remedy whose utilization can be clearly traced (as I did in the address) to the fathers of legitimate medicine.

An Opportunity for the Study of Contagious Diseases.—The Health Department of the City of New York will throw open for competitive examination two positions as Assistant Physicians in the Willard Parker Hospital and the Hospital at North Brother's Island respectively, thus giving an opportunity for the clinical study of the different contagious diseases. Applicants may address Dr. D. M. Stimson, 11 West Seventeenth Street.

Private Establishments for the Care of the Insane in New York State.—The following resolution was recently adopted by the State Commission in Lunacy:

"*Resolved*, that hereafter no license for the establishment and keeping of an asylum or institution for the care, treatment, or custody of the insane or persons of unsound mind, for compensation or hire, shall be granted except to a duly qualified medical practitioner of recognized professional skill and standing, who is a graduate of a legally incorporated medical college, and has had actual experience in the care and treatment of the insane."

Medical Students as Hospital Attendants.—Dr. N. Roe Bradner, of Philadelphia, offers a suggestion to the effect that the service in hospitals and asylums, especially the latter, might be very greatly improved were medical students selected by preference to fill the places of nurses and attendants upon the sick. The students would be content with a moderate salary, since the work would be in the line of their studies, and an opportunity might also be afforded them to attend lectures and to keep up with their reading. The chief objection to such a plan would be the difficulty in so arranging the hours of work in an institution of any kind as to permit the attendants to absent themselves during a large part of the day in order to hear the necessary lectures.

THE JOHNS HOPKINS HOSPITAL BULLETIN is the title of a monthly publication issued under the auspices of the Johns Hopkins Hospital, and containing the proceedings of its Medical Society and various official announcements.

A PAIR OF FORCEPS LEFT IN THE ABDOMINAL CAVITY.—Two prominent surgeons in Pittsburg are charged with having left a pair of forceps in the abdominal cavity of a woman after a laparotomy. The presence of a foreign body was discovered by another surgeon, whom the patient had called in, and the wound was reopened and the forceps removed by him.

THE FRENCH GOVERNMENT has decided that hereafter foreign physicians (more especially English) will not be allowed to practise medicine in France, except "in instances presenting very exceptional claims." This means that the English physicians can no longer undertake to practise in the Riviera, or at the various Mediterranean health-resorts of France. If this rule is to be made to apply to Americans, it would be only fair to undertake reprisals. There are a good many French physicians who come over to practise in this country, and it is a poor rule that doesn't work both ways.

THE REPORT OF THE UNITED STATES MARINE HOSPITAL SERVICE for 1888–89 is a voluminous document, made so chiefly by the official account of the yellow fever epidemic in Florida, and numerous contributions to the pathology of this disease. The clinical and pathological reports are quite numerous, but do not contain much of interest. The work of the Service continues to increase annually, and during the past year 49,518 sick and disabled seamen were relieved, as against 20,922 ten years ago.

DR. THOMAS B. HARVEY, one of the leading physicians of the West, died at his home in Indianapolis, on December 5th. His death was caused by cerebral hemorrhage, coming on while delivering a clinical lecture. Dr. Harvey was born in Clinton, O., in 1827. He was Professor of Gynecology in the Indiana Medical College.

A SUIT BROUGHT BY TYPHOID FEVER SUFFERERS.—During the great typhoid fever epidemic at Plymouth, Pa., in the spring of 1888, which carried off hundreds of people, the Plymouth Water Company were held responsible for the outbreak of the fever, and suits for damages were instituted against the organization by the relatives of the victims. A test case was called for trial for the first time December 10th. Mr. Buckingham, who lost two children, is the plaintiff. He claims $10,000 damages. The company has an able array of counsel.—*Boston Medical and Surgical Journal.*

THE NEW STATE OF WASHINGTON.—The medical men of this energetic young State, says the *Pacific Medical Journal*, are to all appearances wide-awake and hard at work. They have already accomplished splendid results by having engrafted into their State Constitution a provision rendering it obligatory upon the legislature to enact laws regulating the practice of medicine, surgery, and pharmacy in the State. This one successful step puts them in the beginning in advance of every other State in the Union on this important question.

GRADUATES OF AN EASTERN MEDICAL COLLEGE DEBARRED.—A report in the daily papers states that a graduate of Jefferson Medical College was refused license to practise medicine in Minnesota, because the length of that college's term does not come up to the requirements of the Minnesota law. This law requires the applicant for examination for license to practise in that State to have attended at least three courses of lectures of six months each. Each six months' course is reckoned at twenty-six weeks. The course at Jefferson College lacks eight or nine days of the required length.

AT ITS SEPTEMBER MEETING THE VIRGINIA MEDICAL EXAMINING BOARD received twenty-six applications for examination. Sixteen were rejected, two withdrew, and eight were given permits to practise medicine. The low-grade medical schools should advise their graduates not to appear before this Board.

THE NEW YORK DOCTOR'S GIG.—We are told by the *College and Clinical Record* that many of the physicians in New York have recently adopted a distinctive vehicle, a buggy, with a top or hood which is a complete protection from the weather. It differs from a light trotting buggy, as the box is big, roomy, and comfortable, and the hood is arranged in several joints, so that a portion of it may be pushed back at a time. The wheels are almost heavy enough for a light T-cart. The doctors drive two horses, usually handsomely matched, well-built, and stylish animals, with docked tails. The coachman is uniformly in snug livery, with corduroys and varnished boots.

## Obituary.

### CHARLES HENRY NICHOLS, M.D., LL.D.,

NEW YORK.

DR. CHARLES H. NICHOLS, superintendent of the Bloomingdale Insane Asylum, died in this city on December 16th, of cancer of the liver and peritoneum, in the sixty-ninth year of his age. He had been in failing health for several months, and had taken a trip to Europe in the summer, partly in the hope of regaining his strength, but it was only within a few weeks that any apprehensions of a fatal termination to his illness were felt. He was fortunately spared much severe suffering, and the end came quietly as the peaceful closing of a useful life.

Dr. Nichols was born in Maine in 1820, and graduated in medicine from the University of Pennsylvania in 1843. He became assistant to Dr. Brigham in the Utica Insane Asylum in 1847, and soon after went to the Bloomingdale Asylum, where he served as physician for three years, resigning this position to accept an appointment as Superintendent of the Hospital for the Insane at Washington. It was here that the opportunity, which is said to come to most men, came to him, and it found him ready. In the face of much opposition he worked on and constructed, on original plans of his own, a hospital which will long endure as a monument to his genius. About twelve years ago he was recalled to the Bloomingdale Asylum, where he remained up to the time of his death.

Although the equal of any as an alienist, it was as an organizer and as an executive officer that his abilities shone pre-eminent. He was a stern disciplinarian—almost a martinet at times—yet none could ever complain of injustice at his hands, and he possessed the happy faculty of winning and retaining the affection of all his subordinates.

Dr. Nichols' was a well-spent life, and one that reflected honor upon the profession to which he belonged, and his death leaves a void which will not easily be filled.

# Society Reports.

## NEW YORK NEUROLOGICAL SOCIETY.

*Meetings of November 5 and December 3, 1889.*

DR. GEORGE W. JACOBY, PRESIDENT, IN THE CHAIR.

IN March, 1887, a commission consisting of Dr. E. C. Seguin, Chairman, Dr. M. A. Starr, Secretary, and Dr. W. R. Birdsall, together with two ophthalmologists, Drs. W. O. Moore and David Webster, and two other gentlemen nominated by Dr. Stevens, viz., Drs. C. L. Dana and Frank P. Foster, was appointed by the Society to investigate, in conjunction with Dr. G. T. Stevens, the treatment of ocular irritations as a therapeutic measure in certain neuroses. This commission presented its report on the

### TREATMENT OF EPILEPSY AND CHOREA BY THE CORRECTION OF OCULAR DEFECTS

in November, the discussion being concluded at the December meeting. Immediately preceding the reading of the report the following protest was presented by DR. G. T. STEVENS:

"MR. PRESIDENT, AND GENTLEMEN OF THE NEUROLOGICAL SOCIETY: I respectfully protest against the reception of the report now announced, for the reasons: 1st, That the commission, having failed to perform its part of the agreement upon which the report is to be founded, the report is not now in good order; 2d, because the report is not a report on the proposition at issue; 3d, because the report is inconsistent with the facts and is misleading; and, 4th, because it is an *ex-parte* report and objectionable in spirit and motive."

The President then called for the report of the commission, which was read by its Chairman, Dr. E. C. Seguin. The more important features of this report were as follows: After a plan of proceedings had been agreed upon between the commission and Dr. Stevens, the members began to send patients to the latter in April, 1887.

Each patient was examined by two neurologists, who agreed upon the diagnosis and compiled a history of the case. The patient was then sent with the history to Dr. Stevens, who examined the ocular conditions. Subsequently the ophthalmologists of the commission examined the eyes and reported their results to the Secretary, who added these notes to the copy of the history in his possession. When an operation was undertaken, notice of it was sent by Dr. Stevens to the Secretary, and he in turn notified the ophthalmological members and also the neurologist who had furnished the patient. These members then attended the operation and noticed the conditions found in the eyes before and after it, sending their records to the Secretary. Their non-attendance, however, did not prevent operations from being done, and the records of these operations, as well as records regarding prisms and glasses prescribed by Dr. Stevens for the patient, the commission had been unable to obtain from him.

The patients from time to time visited the member of the commission by whom they were sent to Dr. Stevens, and notes of the conditions found were made and sent to the Secretary. In the cases of epilepsy the record of attacks had not in all cases been kept in duplicate, Dr. Stevens having the record on the blanks furnished by the commission, and in these cases the records had not been accessible.

The total number of patients examined by the commission and sent to Dr. Stevens for examination was 28; 23 epileptics and 5 cases of chronic chorea.

All were found to have ocular insufficiencies; 5 were withdrawn without any treatment; 3, a month after examination; 1, two months after; 1, three months after; 2, four months after; 1, five months after.

The reasons for withdrawal were as follows: Five were unable to attend regularly. Two were declined by Dr. Stevens on the ground of organic disease. Five were withdrawn by mutual consent of member sending case and Dr. Stevens, for satisfactory reasons, such as non-attendance. Three were discontented because of increase of symptoms.

Hence of the 28 cases there were only 14 who were treated for four months or over, and these were the only ones available for conclusions. These cases were tabulated as follows, showing the duration of treatment, the date at which the patient was sent to Dr. Stevens, the date of the last report of the condition of the patient, and a statement of the apparent result of treatment.

| Cases. | Disease. | Duration of treatment: months. | Date of first visit. | Date of last report. | Result. |
|---|---|---|---|---|---|
| Elizabeth C... | Chorea.. | 30 | April, 1887. | Oct., 1889. | Much improved. |
| Flora K..... | Epilepsy. | 30 | April, 1887. | Oct., 1889. | Not improved. |
| John M. G.... | Epilepsy. | 5 | May, 1887. | Oct., 1887. | Improved. |
| George K .... | Chorea.. | 29 | May, 1887. | Oct., 1889. | Slightly improved. |
| Aggie H ..... | Epilepsy. | 21 | Jan., 1888. | Oct., 1889. | Not improved. |
| C. D..... | Epilepsy. | 4 | Mch., 1888. | July, 1888. | Unknown. |
| E. F..... | Chorea.. | 8 | Mch., 1888. | Nov., 1888. | Not improved. |
| G. H..... | Epilepsy. | 12 | Mch., 1888. | Mch., 1889. | Improved. |
| David S..... | Epilepsy. | 5 | April, 1888. | Sept., 1888. | Not improved. |
| Eva S..... | Chorea.. | 18 | May, 1888. | Oct., 1889. | Not improved. |
| L. P..... .... | Chorea.. | 10 | July, 1888. | May, 1889. | Improved. |
| Gertrude W.. | Epilepsy. | 6 | April, 1889. | Oct., 1889. | Slightly improved. |
| Mary McK... | Epilepsy. | 5 | May, 1889. | Oct., 1889. | Not improved. |
| Agnes H..... | Epilepsy. | 5 | May, 1889. | Oct., 1889. | Not improved. |

The results could, then, be summarized thus:

| Disease. | Cured. | Much improved. | Improved. | Unimproved. | Unknown. | Total. |
|---|---|---|---|---|---|---|
| Chorea ..... | None. | 1 | 2 | 2 | .. | 5 |
| Epilepsy ..... | None. | None. | 3 | 5 | 1 | 9 |
| Total ..... | None. | 1 | 5 | 7 | 1 | 14 |

Some analysis of the results was necessary. It was evident that six cases were put down as improved. Of these three had been presented to the commission by Dr. Stevens from his private practice, and no exact data had been obtained regarding them. This was especially to be regretted, as the exact degree of improvement could not be ascertained. In the other three reported as improved, the first improvement began in one after thirty weeks, and the patient had never been entirely free from chorea for one month; she had at times been better under the ocular treatment, at times worse, even now having choreic movements, usually before menstruation. In another the chorea was only slightly less than at the outset. The sixth case, an epileptic, was having about the same number of attacks as she had under bromide treatment, but far less than when she had no treatment whatever.

As regarded those not improved, many of the patients would say they felt better in spite of the written records proving the increased frequency of the attacks. This was in part due to increased hope and confidence in the success of the treatment and also to the freedom from depression of mind and bodily functions produced formerly by the use of the bromides. Others had complained much of headache and vertigo which had appeared during the treatment, and in several a condition of diplopia had been produced and now remained. A few of the patients had been made exceedingly miserable by the great increase in frequency and severity in the attacks, which had finally necessitated an abandonment of the ocular treatment and a return to drugs. This statement applied to a number of cases which had been withdrawn.

It would be noticed that none of the cases having been cured, all remained indefinitely under treatment, a perfect permanent ocular equilibrium not having been secured in any case. If it were impossible to secure such equilibrium, a cure could not be expected, granting the theory of Dr. Stevens. If it were possible to secure such equilibrium, it was to be supposed that it could be se

cured in at least two years; yet four of these cases had been under constant treatment for two and a half years without this result.

The following paragraph in the report represents the final conclusions of the committee:

"In view of these facts, your committee cannot but express the opinion that, as far as this investigation has warranted a conclusion, the method of Dr. Stevens does not afford a sufficient degree of relief to patients suffering from chorea and epilepsy to warrant its adoption or recommendation to the members of the Neurological Society as a means of cure or as the sole therapeutic measure."

DR. STEVENS then read a reply to the report of the commission, of which only the outline can be produced here. He said that whatever might have been the original condition of the majority of the cases sent to him during the first year, it was certain that they had long ceased to be cases of functional disease. While, as a matter of fact, everyone of these unfortunates belonged to the class of incurables by any of the ordinary methods of treatment, and while they had grown worse under such treatment continued during many years, they had in every instance under the present mode of treatment materially improved in health and in respect to the special diseases for which they were treated. All this improvement had been brought about without recourse to the deadening results of bromides or the toxic effects of enormous doses of arsenic. The following is a summary of the salient features of Dr. Stevens' reply:

"From the beginning, the commission entered upon its work in a manner entirely inconsistent with the true spirit of inquiry. It pursued it in a manner calculated to induce vexation, misunderstanding, and controversy. It occupied many months in securing a few cases, and has never yet complied with its own stipulations. It has through more than two years occupied itself in selecting the most unfavorable cases for treatment and has taken the favorable cases to itself. The spirit of the report is calculated to produce prejudice and tends to mislead. The report is now made in violation of every principle of right or fairness. The report is represented as an investigation of two diseases and not of a principle, in direct violation of the pledges of the commission. The commission has repeatedly sent cases well known to be unsuitable for the inquiry, and has, contrary to the articles of agreement and contrary to the private promises of members, in this report paraded these cases in long detail with the effect of misleading the judgment of those who are unacquainted with the facts. It has reported the results of treatment of the cases by minimizing the importance of the malady at the beginning of treatment and by magnifying all the unfavorable conditions now existing. The results represented are not in conformity with the actual facts, but are grossly at variance with them. It has reported as resulting from treatment unfavorable ocular conditions which do not exist, and has in this respect made mistakes which, by ordinary care, should have been avoided."

DR. HAMMOND had seen eight of the cases described, in company with Drs. Weir, Webster, Ranney, and Amidon the day before the meeting. The patients and their friends all admitted that the cases had been improved very much by Dr. Stevens' treatment, a fact which was at great variance with the statements made by the same patients to the commission.

DR. SEGUIN said that that part of Dr. Stevens' remarks which reflected upon the fairness and integrity of the commission needed no reply, the names of the members of the commission being a sufficient answer. Dr. Stevens' statements as to the evil effects of the arsenical treatment of chorea, and of the bromides in epilepsy, appeared to pander to popular prejudice, and were altogether unwarranted by fact. Some clinical experience and knowledge of practical therapeutics would have prevented such expressions. Arsenic was almost never harmful to choreic patients, and the evils of bromism could be prevented and corrected by watchful management and appropriate associated treatment.

It was true that the commission had had the greatest difficulty in inducing patients to undergo the treatment, but their failure to obtain twelve cases within the first few weeks was not through neglect or violation of the agreement. It was simply an impossibility to supply the necessary material in a given time: enough had been furnished in all. Dr. Stevens, in not furnishing data as to the course and progress of the cases as stipulated in the agreement, had violated the compact. The report had no personal animus and was not made up of the ideas of any one or two members. It expressed the opinions of all of the members of the commission, even of those selected by Dr. Stevens himself.

As regarded the statements of friends and relatives in medical investigations, these should be received with scientific doubt, particularly when they differed from the facts as shown by the commission.

As far as his own cases were concerned, one had been nearly killed by the ocular treatment involving the omission of bromides, passing into a status epilepticus, but improved again under bromides. Another had been under ocular treatment for fifty-two weeks before improvement became marked. Another, the girl with chorea, showed no tangible improvement until after the lapse of seven months. His own experience in cases of chronic chorea, even when of five to seven years' duration, was that they were not merely improved very soon under arsenical treatment with rest in bed, but, as a rule, cured in from two to three months. This girl, though improved under the ocular treatment, had now transient diplopia for far and near, while the second case alluded to saw double at the present time on looking to the right. The improvement in these cases (which were the best of the series) could not therefore be ascribed to the ocular treatment, but was to be attributed to improved health and time. Dr. Stevens had reported fifty per cent. of cures of epilepsy in his own (former) series of cases, but in the cases examined by the commission there was not one. Moreover, he had reported his cures as taking place in a few weeks after beginning the ocular treatment, while in these cases, where improvement of any kind had taken place, many months had been required before decided change had been manifested.

DR. STARR, in regard to the remarks made by Dr. Hammond, referred to the records of the cases already read to the Society, which demonstrated in each case an increase in the number of attacks, in some of them to three times as many as formerly. It was well known that the statements of epileptics were unreliable concerning their own seizures, and in several of these cases it was evident from their own records of their attacks that any statements they had made that they were better were in direct opposition to the real facts. The recollections of such patients regarding their past states could not be considered as at all comparable with the actual observations taken during such periods.

In one case, pronounced by Dr. Webster as normal ophthalmologically, and in every respect a purely functional case, Dr. Stevens claimed to have found optic atrophy, and called it an organic disease.

DR. BIRDSALL had seen an epileptic, one of the cases mentioned by Dr. Hammond as having reported improvement to him, and whose sister corroborated the patient's statement. He had asked the sister why she had made this statement. She had replied that she did not refer to the number of fits, which was unchanged, but meant that the patient seemed to be brighter without the bromides. The record showed, however, that the number of attacks had increased, and that the patient was in reality much worse under Dr. Stevens' treatment.

DR. DANA said he had been nominated for the commission by Dr. Stevens himself, and felt that he represented him in a measure, but naturally his chief object had been to obtain the exact truths in the matter. He had

sent twelve cases of his own to the commission, and had tried hard to get others to go. He had made every effort to get suitable cases, but he had seen no case much improved under Dr. Stevens' treatment. One case seemed to be improved, but he could not feel sure that improvement was due to the ocular treatment. He had lost most of his faith in it as a therapeutic measure. We ought, however, to pay some tribute to Dr. Stevens for perfecting the technique in his procedures, even though he had pushed his theory to extravagant conclusions.

Dr. Stevens said that when the investigation was commenced, cases were accepted by the commission which ought never to have been taken. One was a pronouncedly organic case, and, in fact, not one of the cases was functional.

Dr. Webster stated that the diplopia now existing in one of Dr. Seguin's cases did not amount to much. It was trivial. He had seen Dr. Stevens operate many times, and had learned very much from him as to the technique in the treatment of insufficiencies. Dr. Stevens had, moreover, greatly improved the nomenclature in this direction. Not being a neurologist, he did not feel able to judge of the therapeutic effects of the operations in these cases.

Dr. Stevens said that the operative technique was exceedingly delicate and difficult, and that the greatest skill was required, such that he did not claim yet to have himself attained; but the more skilful the operator becomes, the more valuable will prove to be this therapeutic measure.

Dr. L. C. Gray had listened with interest to the report and its discussion, and was wholly unprejudiced on either side. He did not believe that Dr. Stevens had substantiated his serious charges against the commission, or caused any particular improvement in the cases. Esquirol showed in 1828 that temporary improvement took place in all cases of chronic epilepsy in La Salpêtrière when treated by drugs known at that day. A decrease of from six to three fits daily could not be considered a permanent improvement, because such decrease was often spontaneous, and, in some cases, fits spontaneously ceased for years. He agreed with Dr. Seguin that where improvement did not begin before fifty-two weeks after treatment had been begun, any improvement that might take place could not fairly be ascribed to the measure employed. If Dr. Stevens had claimed merely that headaches and other trivial neuroses had been relieved by his method, many of the gentlemen present would have coincided with him; but he had undertaken too much, and was extreme in his claims. The same therapeutical principle underlay his system as that of Sayre, who cut prepuces, and that of the English surgeon who amputated clitorides for the cure of the slighter neuroses.

Dr. Amidon said that he had been invited, with a number of others, by Dr. Ranney to see the cases described at Dr. Stevens' office, and they had the complete histories of the cases at the time upon which to form an opinion. He intended to oppose the acceptance of the report of the commission, for it was clearly apparent that Dr. Stevens had brought about improvement in these patients without resort to medication, which was more than any of us could do.

Dr. Seguin said, with reference to the work done by Dr. Stevens, that all of the members of the commission had appreciated it highly and had felt like adding something commendatory of his skill to the report, but refrained from so doing because, under the circumstances, it might have appeared hypocritical, and was really alien to the subject assigned to the commission, viz., the determination of results.

Dr. J. L. Corning thought that Dr. Dana's tribute to the good work done by Dr. Stevens was in exceedingly good taste. Dr. Stevens' work was unusually scientific and original, and there seemed to be very little of that sort of work done in New York, where compilation and the importation of foreign ideas were the order of the day. Hence this discovery of Dr. Stevens ought to meet with wide recognition.

A motion to adopt the report of the commission was then carried by a vote of five to four out of the eighteen members present, the members of the commission refraining from casting their votes.

The following motion, made by Dr. Amidon, was unanimously carried:

"That the thanks of the Society be extended to Dr. Stevens for the assiduous labor he has devoted to the work of the commission, and that the Society assure Dr. Stevens that it highly appreciates the ingenuity and technical skill he has shown in the prosecution of his method."

Besides the report of the Stevens Commission, the following contributions were made at the two meetings of the Society.

Dr. Ira Van Gieson read a paper entitled

A CONRTIBUTION TO THE PATHOLOGY OF THE LARYNGEAL AND OTHER CRISES IN TABES,

and described a case of tabes with laryngeal attacks during the last year of the illness. One of the crises proved fatal. Microscopical examination showed the lesions of a chronic neuritis of the roots of the vagus and accessary portion of the spinal accessary nerves on both sides. Neuritis of the root-fascicles or trunks of one or both of these was regarded as more frequently the cause of the laryngeal crises than central lesions.

The author divided laryngeal crises into two classes: A first class in which the glottis constrictors and dilators were normal, and the crises occurred by reflex spasm of the adductors; a second more numerous class of cases, in which the constrictors and dilators are in a greater or less degree of paralysis.

The first form of the crisis might be produced by a neuritis of the roots of the accessary portion of the eleventh nerve, irritating the sensory fibres of the larynx, and being responded to by motor impulses through the vagus, which would produce closure of the glottis by contraction of the adductors. The second form of the crisis might be produced by a destructive stage of the neuritis in the vagus, inducing a motor inability of both the adductors and abductors. But as it has been shown experimentally, in animals, that the adductors are stronger than the abductors, a reduction of power in both sets of muscles would render the equilibrium of the two sets of muscles so unstable that reflex irritation of the motor laryngeal fibres, or direct irritation of these fibres in the vagus by the neuritis, would be responded to by a contraction of the stronger adductors, analogously to the results of artificial stimulation of the motor laryngeal fibres in animals. When the neuritis affects both the vagus and accessary nerves together, the conditions are favorable for the production of violent crises. A localization of the lesions causing the other crises in tabes was based on Gaskell's description of the distribution of the sympathetic system.

Dr. A. Schapringer presented a case of

CONGENITAL BILATERAL ABDUCENS PARALYSIS WITH FACIAL PARALYSIS.

The patient was a girl, eight years of age, with congenital paralysis of both facial nerves, and inability to rotate the eyeballs either to the right or to the left. The faculty of rotating the eyeballs upward and downward was unimpaired, and so was the faculty of convergence. This condition of the motor apparatus of the eyeballs is termed by certain authors "bilateral abducens paralysis," which designation Dr. Schapringer considered insufficient and misleading, and he therefore proposed the term "bilateral pleuroplegia" as a substitute. There were only four similar cases on record, viz., one each described by Alfred Graefe, G. C. Harlan, Julian Chisolm, and P. J. Moebius. Other co-existent anomalies present in the child exhibited were: A protuberant glabella, bilateral epicanthus, a slight deformity of the terminal phalanx of the left index-finger, a bifid uvula, and a sunken sternum, representing a rudimentary form of "funnel chest" (*Trichterbrust* of the

German authors). There was also a partial implication of the motor portion of the fifth and of the hypoglossal nerves.

Dr. Schapringer considered the phenomena within the sphere of the cranial nerves as due to a lack of development of the brain involving the nuclei of the fifth, sixth, seventh, and twelfth nerves.

Dr. Sachs was acquainted with the case reported by Moebius, which, however, differed from this in that there were four nerve-nuclei affected in the latter. It was a question whether this was a congenital condition or a poliencephalitis superior occurring shortly after birth. He referred to a case of his own of congenital bilateral ptosis, and thought it was probably similar to those just described.

Dr. Seguin had observed such a condition to follow traumatism. A lady, ten years ago, was thrown from her carriage, and made unconscious for several hours. She had a double abducens paralysis, lasting several years. He thought there was hemorrhage into the nuclei of these nerves.

Dr. Corning had seen a case precisely like that of Dr. Seguin following a blow upon the neck.

Dr. Birdsall described a case of double abducens paralysis, occurring in a man whose head was caught between two car-buffers.

Dr. Schapringer said he had frequently seen cases of double abducens paralysis, but that he knew of only four where there was in addition disease of other cranial nerve nuclei.

Dr. C. A. Herter read the clinical history and report of the autopsy in a

CASE OF CERVICAL PARAPLEGIA FROM DISLOCATION.

J. F——, a mason, fifty-seven years of age, fell head first from a scaffolding, a distance of twelve feet, striking with his head against a board. Patient was conscious on admission to the hospital. Examination failed to elicit evidence of fracture or dislocation in any part of the cervical spine, but there was great tenderness of the sixth and seventh vertebræ. There was complete motor paralysis below the arms. The forearms and arms were normal, but there was weakness of the muscles of the hand. There was also anæsthesia and analgesia of the lower extremities; and of the trunk extending high up on the chest. On the arms the anæsthesia involved, roughly speaking, the distribution of the ulnar, internal cutaneous, and lesser internal cutaneous nerves, and was highly symmetrical.

With the exception of the plantar reflex of the left side, both superficial and deep reflexes were absent when the patient was admitted. There was a cincture pain about the lower part of the neck, and above and below the clavicles there was hyperalgesia. Below the neck there was pronounced myoidema, and fibrillary contraction could readily be elicited. Respiration was purely diaphragmatic. Temperature on admission, 97.2° F. Retention of urine, and incontinence of fæces.

Nine hours after admission it was found that the sensory loss was the same as before, but the motor paralysis had spread so as to involve the flexors and extensors of the wrist, the triceps, and, to a less extent, the pectoralis major, and the pronators and supinators. Very slight power remained in the biceps. At the time no reflex could be obtained. Respiration continued diaphragmatic. The pulse was somewhat feebler than on admission, but good. The temperature had risen during the afternoon following admission to 104° F.

On the day following admission the patient's condition was about the same, except that the biceps was somewhat feebler. During the afternoon of this day there was some embarrassment of respiration, and on the second day after admission the patient died from respiratory failure, having survived the injury forty hours.

The autopsy, which was conducted after death, revealed a dislocation forward of the sixth cervical vertebra, and an oblique fracture through the left superior articular process of the sixth vertebra. The forward displacement of the sixth vertebra was probably not more than one-third of an inch. How much pressure was being exerted on the cord at the time of the autopsy could not be determined. Examination of the cord showed that the eighth cervical segment was extensively disintegrated, and that the seventhwas considerably softened by the displacement of the vertebra. At the junction of the sixth and seventh segments the central canal was distended by hemorrhage and there seemed to be some extravasation into the surrounding gray matter. Above the sixth segment the cord was normal. The case supported the view that the peculiar distribution of the sensory disturbance noted in the upper extremities depended on a lesion of the eighth cervical and first dorsal segments, and that in this case the biceps was represented at a lower level than is considered usual, *i.e.*, in the lower part of the sixth segment.

Dr. Starr said our knowledge was not yet complete with regard to localization in the cord, and every such case was very valuable. In his table he had located the biceps-nuclei in the fourth segment because it was so often associated with the deltoid in paralysis, and this was the level of the latter muscle. It seemed, from Dr. Herter's case, that the biceps-group of cells had a vertical arrangement of greater length than he had supposed, extending probably from the fourth down through the cord as low as the seventh segment.

Dr. Herter thought that the nuclear arrangements might differ in various people, and in his case the biceps-nucleus may have been lower than usual.

Dr. Dana hoped that Dr. Herter would examine his experiments with Dr. Abbe in two cases where, in operations upon the spine, he had applied electricity to the nerve-roots, and shown that there was much more overlapping of cell-groups than was ordinarily supposed.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, December* 5, 1889.

Alfred L. Loomis, M.D., President, in the Chair.

The following nominations were made: For *Vice-President*, one to be elected, Drs. R. C. M. Page and Joseph D. Bryant; for *Trustee*, Dr. Laurence Johnson; for member of *Committee on Admissions*, full term, Dr. A. Caillé—short term, Dr. French, of Brooklyn; member of *Committee on Library*, Dr. Egbert H. Grandin.

Dr. J. D. Bryant read a paper on

THE HEALTH DEPARTMENT AND THE CONFERENCE COMMITTEE OF THE ACADEMY OF MEDICINE.

The subject of the paper, he said, was certainly of great interest to the Health Department (of which he was a member), and should be of interest to the medical profession of the city. He knew of no good reason why legalized action for the prevention and treatment of disease, as embodied in the Health Department, should not receive the earnest support and hearty co-operation of that profession, which sought the same end, although by somewhat different means. It was true, no doubt, that unavoidable friction would here and there arise, but "friendly and considerate friction makes good friendship brighter and keener, while unkind and thoughtless opposition darkens, dulls, and often destroys it, substituting confusion for order, defeat for victory, disaster for success, and not infrequently death for existence."

The Commissioners of the Health Department recognized the need of the sympathy, advice, and support of the medical profession, and he thought no wiser thing had been done than when, at its suggestion, two years ago, the Academy appointed a conference committee to confer with it, consisting of five members. The gentlemen then appointed were Drs. Agnew, Janeway, Stephen Smith, and Derby; the then president, Dr. Jacobi, also becoming a member. Valuable suggestions and aid had been rendered by this committee and the pathologists of the department, Drs. Prudden, Biggs, and H. P. Loomis, in

matters concerning quarantine against imported disease, diagnosis of Asiatic cholera based on bacteriological investigations, the getting up of a disinfectant plant situated at the Willard Parker Hospital, the prevention of tuberculosis, etc. A warm compliment was paid Dr. Agnew, who, as a member of the Conference Committee, had manifested his usual devotion to the public welfare at the sacrifice of personal interests. The department had not only established a disinfectant plant at the Willard Parker Hospital, where infected material could be promptly and safely destroyed, but it was its purpose to found disinfecting laundries where infected textile fabrics could be disinfected and returned to the owners. The author gave a condensed statement of some of the work done by the department, with the aid and advice of the Conference Committee, since its appointment in 1887. The number of buildings inspected during that time, in which there had been contagious diseases, was (we give the round numbers) 35,000. Of the forms of disease, there were a few cases of typhus fever, 2,000 typhoid, 16,000 scarlatina, 10,000 measles, 13,000 diphtheria, 285 cerebro-spinal meningitis, 216 small-pox, 878 phthisis, 128 tubercular meningitis, 52 dysentery, 61 malaria, 23 tabes mesenterica, 4 entero-colitis; total, 44,000. The number of rooms fumigated was 33,000; number disinfected, 116,000. It was not uninteresting to note that $SO_2$ was as good an agent for disinfecting as any. It would be noticed that the department was investigating the question of contagion and spread of tuberculous disease, and if it found sufficient reason for it, physicians would be requested to report cases coming under their notice, and like precautions would be taken as in certain of the contagious fevers. Visiting houses where contagious diseases existed had led to eight thousand complaints of the sanitary condition present, which otherwise would not have been reported, or at least not so soon.

During the thirty-two months ending with November 1st, over one thousand cases of contagious diseases had been received at North Brother Island Hospital, and 1,780 at the Willard Parker Hospital. In the latter hospital the mortality rate in scarlet fever in children, out of 425 cases treated, was 20.7 per cent.; diphtheria, 519 cases treated, 20.85 per cent. At North Brother Hospital, small-pox, cases treated over 300, mortality rate 19.69 per cent.; scarlet fever in adults, cases 361, mortality rate 10.87 per cent.; measles, about 200 cases treated, mortality rate less than seven per cent.; whooping-cough, cases 32, mortality rate 16.62 per cent.; typhoid fever, cases 4, mortality rate seventy-five per cent. A few cases of typhus, mumps, chicken-pox, all recovered. Out of 1,001 cases treated, the average mortality rate had been 13.49 per cent. These results compared fairly with cases treated outside in the city of New York from January 1, 1888, to November 9, 1889, as follows: Scarlet fever, cases (round numbers here given) 14,000, mortality rate 16.44 per cent.; diphtheria, cases 11,000, mortality rate 29.33; measles, cases 13,000, mortality rate 7.77; typhoid fever, 2,300, mortality rate 26.63; chicken-pox, cases 16, mortality rate 31.25 per cent. These were the only diseases which could be used for comparison. He added that the four cases of typhoid fever admitted to North Brother Island Hospital were very severe cases when they entered.

In the vaccination department, the total number of vaccinations in 1888 had been 83,000; of the primary vaccinations eighty-three per cent. had been successful; of the secondary vaccinations 47.5 per cent. had been successful at the first attempt, and twenty-four per cent. at the second attempt. The figures for 1889, as far as they had been made out, were in nearly the same proportion. During the past five years the record of births per year had averaged 32,407, while the number of primary vaccinations by the department had averaged over 24,000 per year. He said it would thus be seen that the city was well protected against small-pox.

The importance of having in the city sufficient and suitable accommodations in which cases of contagious diseases could be treated among transient people and others who, by reason of their affluent circumstances, could avail themselves of the attention which they would like to receive, and were excluded from hotels and private houses, should be given most earnest consideration. This became more important in view of the proposed International Fair, should it be held here.

Other work done by the department had been to thin out the overcrowded rooms in the Italian districts. The population of such crowded rooms had been reduced during the past sixteen months by seven thousand people.

The prevention of the adulteration and sale of unwholesome food had not been lost sight of by the department. In less than two years it had condemned and destroyed 17,741 quarts of milk, 827 tons of fish, 428 tons of meat, 1,546 tons of fruit and vegetables. The arrests and fines made in connection with these seizures had proven somewhat salutary, as was shown by the following statement: In 1888 there were 450 arrests, with fines amounting to $13,027; in 1889, to November 1st, there had been only 264 arrests, with fines amounting to $8,835.

Since 1879 the Department had had the power of approval or disapproval of all plans for the construction of tenements and lodging-houses, as related to light and ventilation; also the approval and disapproval and supervision of all changes made in buildings to be used as tenements or lodging-houses, as regarded light and ventilation; and since 1881 the department had had the approval and disapproval and supervision of the plumbing of buildings erected in the city. This involved great responsibility and labor, and a high degree of special knowledge and vigilance on the part of those engaged in the work. The last two years, ending with November 1, 1889, the plumbing plans supervised had been 3,157; light and ventilation, 1,935; covering, so far as concerned plumbing, over 6,000 houses, and for light and ventilation over 3,500 houses.

It was not necessary to speak of vital statistics, with which the profession was already familiar, and other details which would grow wearisomely long. It would be of interest, however, to state that the Health Commissioners contemplated the enforcement of an approved method of the disposal of stable manure on or about the 1st of May. The permanency of position and promotion of those engaged in the service of the department would depend upon the faithfulness and ability with which they discharged their duty. The department requested the earnest support of the profession and laity in the discharge of its duties, and requested that the vacancy in the Conference Committee made by the death of Dr. Agnew be filled, and that the President of the Academy be always a member.

Dr. A. Jacobi, being requested to open the discussion, said he hoped that at the proper time two motions would be introduced and prevail. (They were introduced and adopted later as new business, making the President a member of the Conference Committee, and requesting Dr. Bryant to read a report on the disposal of manure at the next meeting of the Section on Public Health and Hygiene.)

Dr. Jacobi went on to say that he was ever of opinion that every man had a right and a duty to give the very best he had in the service of the community. Now, the best which the Academy had was its collective knowledge. He was not at all of the opinion that every individual physician was an expert in everything that might pertain to the Department of Public Health, but he did know that the medical profession, as represented in the Academy of Medicine, was and ought to be expert in everything medical. He included among things medical dietetics and hygiene, in all their aspects. When, as President, he invited Dr. Bryant to read his paper before the Academy, two years ago, in which it was suggested that a conference committee be appointed, he knew that the Academy would certainly show its willingness to aid the Health Department, and it had done so whenever it had been expected of it.

The Academy had been recognized for some time as representative of the medical profession in this city, and justly so, and the medical profession had been recognized as at least fit to be associated with the Public Health Department. It was known that for a long time past a medical man had been a member of the Health Department. That was not more than could be expected. But something more might have been expected. For instance, there was a law forbidding a medical man being president of the Department of Public Health. Some were of opinion that that was a good law; many of the profession believed that it was not; but this much was sure, that for a good many years past the men at the head of the Health Department had done everything in their power to facilitate the work of the medical men who had charge of medical matters. We had all been in contact a good deal with the former president of the Board of Health, and had found that he was efficient and willing to serve the interests of the community; and he knew from the very best possible source that the present incumbent tried to obey the same law, and left medical matters in charge of the medical member; and on this fact the Health Department, the public, and the medical profession could be congratulated.

He wished to make a few suggestions. First, that the attention of the department in the future be directed to a part of the furniture of buildings inspected for their general sanitary condition, or because of the presence of contagious disease within their walls. For instance, in tenements and flats occupied by eight to twenty families, the stairs would be found covered with carpet which became the receptacle of all sorts of disease-germs, including such contagious diseases as scarlet fever, diphtheria, etc. He approved of the author's remarks on the need of a hospital for the reception of strangers and others taken down with contagious diseases, and said he thought there was need of as many as a score throughout the city for all classes, citizens and strangers. A child with diphtheria was exposed to repeated attacks when confined to one room in order to isolate it from other members of the family; relatives and friends feared to receive it when convalescent, as they did also its healthy brothers and sisters. It would be well to have a quarantine station at which the healthy members could be received for a time until danger of contagion in their homes could be removed.

Mr. C. C. Wilson, president of the Board of Health, said: Thanks for your kind invitation, I have been able to listen this evening to the reading of a paper upon a subject which is most interesting to me at the present time, namely, the best means of enabling the Board of Health to promote the well-being and the good of the people of the city of New York. It seems to me, from the position taken by the author, that the paper admits of scant criticism. From observations made during the six months I have been connected with the Health Department, and from a careful investigation of its records since 1873, I am convinced of the wisdom and necessity of maintaining close relations between the medical profession of this city, the Conference Committee of the Academy of Medicine, and the Board of Health. Your honorable body is not only well abreast the science of the day, but it makes it practical, and transforms the dream of the theorist into the reality of the philanthropist.

The powers of the Board of Health are ample, but it needs at all times your active co-operation and support. It has been well said that all laws are but as ink and parchment unless supported by public approval, and in your special province no class or profession wields so powerful an influence, and is so widely heard, as yours. Hence we welcome suggestions from you as to what is best, and join hands heartily with you in breaking down prejudice and objection. With your aid, the Board of Health will be enabled at all times to strike telling blows at the foundation of disease.

Without going into details, the several bureaus of the Board of Health are so constituted, in my opinion, especially with regard to the hospital service, and the bureau of contagious diseases, as to be ready at all times for any emergencies they may be called upon to meet. For myself, I have mapped out a course since I have had the honor to act as one of the Commissioners of Health, and that is, to stand shoulder to shoulder with my colleagues, while managing the department as economically as prudence suggests. While doing this, let me assure you, one and all, and I know I voice the sentiments of my associates, every suggestion of your Conference Committee will be well and favorably received and considered, and carried out if possible. Thus favored with your advice and moral support, who shall say that, of all great cities, ours is not only the one from which disease and pestilence is shorn, but also the one most blessed with that happiness which springs of freedom from suffering.

Dr. D. B. St. John Roosa said he thought it would not be considered offensively eulogistic, inasmuch as he would later have something to say which could not at all be considered in that light, if he remarked in the beginning that, no matter what else we may have been fortunate in in the Board of Health, we had been extremely fortunate in the medical men who had represented us. But, he said, he had not come to the meeting in any complacent mood. He was not satisfied with the condition of things in New York. He considered the great work done by the Board of Health (and no man appreciated its greatness more than he did) as but rudimentary. Every city that maintained itself at all in the category of decent cities ought to superintend the meat and milk, the tenement-houses, to vaccinate the children—those things which had been done so well here. Dr. Jacobi had said that the medical matters of the Board were referred to the medical member. But there was not a matter, from A to Izzard, which came to the hands of the Board of Health, which was not a medical matter, and the majority of the Board ought to be medical men. The present law, which said that a medical man could not be president of it, was an offence to the profession. The distinguished president of the Board had said that the powers of the Board were ample. He was glad to hear it. Yet, with all this power, we had to wait until the 1st of May for the correction of the manure nuisance. Besides, in this matter he would say, with due respect to the Board, that he would believe when he saw. Then, consider the condition of our streets. Yet he had never even heard it suggested that the Board of Health ought to do anything about that. He would advise more ample powers. And so of the death-dealing electric wires, the subways, etc.

Dr. E. G. Janeway remarked that there were two sides to every question, and if he might say a word *apropos* of the remarks of the last speaker, he might assert that there were two sides even to the manure question. There were certain controlling methods by which the Board of Health was alone able to exist and retain its powers. If it should attempt to carry out all that the law had given it power to do, it would soon kill itself. Arbitrary and radical measures, carried out in a way to compel changes in an instant in the method of doing things, would be impossible, or would arouse such public indignation as would crush the Board and put it out of existence. Some of the most urgent criticisms upon the Board which he had heard came from medical men. We made those criticisms when the matter came home to ourselves, but when it concerned other people we wanted to see radical and instantaneous relief. In the matter of co-operation, there was no doubt a great deal could be done by the medical profession in assisting the Board of Health. It could be done in two ways: by kindly assistance, and withholding invidious criticism. Regarding the founding of other hospitals for contagious diseases, he said there would be great difficulty in selecting a site, as there was in the case of the Willard Parker Hospital, neighboring property owners and others objecting even where grounds could be purchased. In the event of the International Fair being held here, a hospital should be estab-

lished near, but not on, the fair grounds. As to the electric wire question, it had been settled that power rested in another department. Finally, he would suggest to those who had criticisms to make on the actions of the Board, that they make them to the Board, and in a spirit to assist in correcting the evil; or, if their impressions were erroneous, to have themselves set right, and thus avoid unnecessary irritation. Let none recommend persons for a position in the department for whose fitness he could not personally vouch.

Dr. Daniel Lewis said that in past years he had himself thought an injustice was being done physicians in disqualifying them by law for the presidency of the Board of Health. But since he had become better informed of the duties of that office, he had come to the conclusion that it would be utterly impossible to secure a physician of repute in this community who would take it and perform all the duties pertaining thereto. For instance, would Dr. Roosa be willing to go down at nine every morning and remain in the office three hours looking over coal bills, signing checks, and the like? It was true, as he said, that these matters were all medical, but they were attenuated to the third and fourth dilutions. He for one was satisfied, for he believed we had a Board of Health with which we might and ought to co-operate. Regarding the powers of the Board, they were no doubt ample, and the danger was that it might exert those powers to the full extent. At least that was the fear of some citizens. Take the hospital for contagious diseases, there were many parents who objected to having the presence of scarlet fever in their family reported, through fear their child might be taken from them and placed under the care of a strange physician and strange nurse, and for that reason they sought to evade the law and not have the case reported. Nor was it conducive to recovery to have these little patients transferred in an ambulance from Harlem down to Sixteenth Street, to the Willard Parker Hospital. Thus it was evident that in all the Board of Health did the public interest, the interests of individuals, must be taken into consideration. The percentage of recoveries from contagious diseases outside the hospitals was probably greater compared with that in the hospitals, given by Dr. Bryant, for the reason that many cases without recovered, not having been reported at all.

Dr. H. J. Biggs wished to call attention to the fact that the action taken by the Board of Health, with regard to infectious diseases, showed that in this respect it was fully abreast the most advanced ideas on the nature of these diseases. This was shown in its providing for the disinfection of clothing, its investigations regarding the best method of preventing the spread of tuberculosis, etc. Yet there was probably only a small proportion of the profession who yet took practical note of the fact that tuberculosis was contagious.

Dr. Cyrus Edson, of the Health Department, said, in order to prevent misapprehension, that the department did not take children to the hospital without consent of their parents, unless great danger to others was incurred by leaving them at their tenement-homes. As to new hospitals for contagious diseases, he said the difficulty of obtaining sites might be met by erecting separate buildings on the grounds of present hospitals. Mount Sinai Hospital, for instance, had a good ward for contagious diseases, as had also the Nursery and Child's Hospital.

Dr. Bryant said, in closing the discussion, that the danger of the Health Department taking charge of the street cleaning, if it could do so, would be in its going beyond that work which was recognized as coming directly under sanitary matters in the accepted sense of the term, and not in the broad sense of the term which Dr. Roosa had mentioned. With regard to the electric wire, counsel had decided that it could not interfere. Regarding the Willard Parker Hospital, they had good nurses there to take care of the little patients, but mothers could come if they wished, and could send the family physician to take charge of the patient.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Adjourned Annual and Stated Meetings, November 25, 1889.*

Alexander S. Hunter, M.D., President, in the Chair.

Julius Althaus, M.R.C.P., and Henry Morris, L.R.C.S., London, were elected to honorary membership.

The President read a brief address, in which he expressed appreciation of the renewed expression of confidence shown in his re-election, stated that essentially the policy of last year regarding scientific work would be adhered to, and made some strictures upon the medical journals in their relations to the societies. He then appointed the following

### COMMITTEES.

Committee on Ethics—Dr. E. L. Partridge, Chairman; Drs. H. E. Crampton, O. B. Douglas, A. M. Jacobus, and E. S. Peck. On Hygiene—Dr. Simon Baruch, Chairman; Drs. R. C. M. Page, J. E. Janvrin, Cyrus Edson, and Henry D. Chapin. On Prize Essays—Dr. L. Bolton Bangs, Chairman; Drs. E. H. Grandin and Andrew F. Currier. Auditing Committee—Drs. William Stevens and R. M. Fuller.

Dr. Malcolm McLean then read a paper (see p. 676) entitled

### CONSERVATISM IN GYNECOLOGY AND OBSTETRICS.

Dr. Thomas Addis Emmet fully indorsed the views expressed by the reader of the paper. The pendulum, he said, had swung far enough in one direction, and it was certainly time for it to begin to return. He had fought the extreme tendency toward operative interference, shown especially by the younger members of the profession, for some years, and felt that in doing so he had about lost caste. By some of his younger friends his want of appreciation had been attributed to advancing age, but he himself did not think this could be true, since he felt even more eager to learn now than he did twenty-five years ago. So far as the gynecological abuses which had called forth a paper of this nature were concerned, especially in the direction of removing the tubes and ovaries by surgeons in this country, he felt himself somewhat responsible. It was six or seven years ago that he was in Europe, and hearing Mr. Tait much spoken against in London he thought it probable some injustice was being done him, and, although he had no personal acquaintance with him, he went to see him, was received with marked courtesy, and became convinced from what he observed that he was doing a good work. He showed him about seventy-five or eighty pairs of tubes put up in bottles, with full histories, and gave him opportunity to see some patients operated upon, and there seemed to be no question that the condition present demanded the operation. Dr. Emmet was given some specimens, which, on his return, he presented at the first meeting of the Obstetrical Society, and indorsed the operation. Up to that time it had been practically unknown in this country, but he fully expected within a week to find a case demanding it. Three years, however, passed before a case presented itself to him in which he thought the operation was justifiable, but in the meantime, in the hands of the younger men it had spread like wildfire on a prairie, and he had to turn and fight it in its destructive progress. One of his younger friends had said that he was honest, but was getting too old to learn anything new. Certainly there were cases of pyosalpinx of clearly gonorrhœal history which could not be relieved in any other way than by an operation, but they were very few. He had found that over fifty per cent. of the cases which had come to him after other surgeons had said they could not get well without removal of the tubes and ovaries did get well at his hands without an operation. He could recall such a case even in which the origin of the tubal disease could

be clearly traced to gonorrhœa, yet the patient subsequently conceived and bore a child. Indeed, many of the cases in which removal of the tubes and ovaries had been pronounced a necessity would get well without any treatment whatever at the hands of a physician. Nature would sometimes cure a pyosalpinx as she would cure any abscess, by adhesive inflammation after discharge of the tubal contents had taken place through the uterus. Regarding too frequent removal of the ovaries, he had never sanctioned their removal except for malignant disease or cyst.

He had at one time ceased his attendance on the Obstetrical Society because it had come to be really an ovarian society, a soup-plate full of ovaries being served up at every meeting, many of which were simply undergoing the vesicular degeneration pertaining to their normal function, and he was unwilling to admit the position that it was necessary to spay a woman in order to cure her of nervous symptoms which he claimed were due to impaired nutrition or anæmia. Such an admission was a reflection on our skill as physicians. He had cured many such cases, but some men seemed to be too lazy, or lacked the skill to carry out the necessary steps, and save the patient from the mutilation of the knife. In the operation for repair of the cervix with which his name had been connected, surgeons so often exhibited such impatience, or lack of skill, or want of judgment in the selection of cases, that he sometimes thought the operation had in the aggregate done more harm than it had done good. In dysmenorrhœa, gynecologists were not satisfied to cut the cervix, but must tear it open even by the most violent means; yet if his experience of forty years had taught him anything, it was that obstructive dysmenorrhœa was only a myth; that the dysmenorrhœa was due to impaired nutrition of some form. He might thus go on criticising meddlesome gynecology indefinitely, did time permit. He would mention one point in regard to conservatism in obstetrics. The Woman's Hospital was first founded for the treatment of vesico-vaginal fistula, and there came under his charge, either directly or through the service of Dr. Sims, over five hundred cases. In analyzing them some time ago he was surprised to find that the cause was, in nearly all instances, not instrumental delivery, but delay. It taught a valuable lesson, namely, that it was very dangerous to delay the use of the forceps when they were called for. As soon as impaction took place, the sooner the woman was delivered the better. Mr. Barnes, of London, had written him several years ago rather reflecting on our skill as obstetricians in this country, since one man had seen as many as five hundred cases of vesico-vaginal fistula, but, on looking up the histories of those cases, Dr. Emmet found that fifty-eight per cent. of them were immigrants recently landed from Europe, especially parts of Ireland where they were too poor to obtain proper medical service.

Dr. H. C. Coe said he had been strongly impressed by a concluding sentence in the paper bearing on the proper instruction to be given at the postgraduate schools. He had found in that field that conservatism in gynecology was an exceedingly unpopular position to take. In fact, one who took that stand on days when the hospitals offered an opportunity to witness a laparotomy was likely to be mortified on entering the lecture-room to find many vacant seats. It seemed to him we were in danger of forgetting that laparotomy constituted only a very small part of gynecological practice. It had been his constant attempt to impress students with the fact that when they returned home they would probably have ten cases of retroflexion of the uterus to one of laparotomy; probably the ratio would approach more nearly ninety-nine to one. He had discussed the pathological side of the question pretty thoroughly several years ago, and in doing so had come pretty constantly in collision with Mr. Tait, yet he had not found any reason to alter his views. His stand was that removal of many of the tubes and ovaries, exhibited at the societies, was hardly justified by the findings of the pathologist. He believed, however, that there were now far fewer uterine appendages removed which were only slightly diseased than there were three or four years ago, and he further believed that four years hence the number would be much smaller still. He firmly believed that the triumphs of the future were going to be in other fields than laparotomy; that extra-uterine fœtation, retroflexion and fixation of the uterus, etc., would become of greater interest because of being met with every day, even by the general practitioner.

Dr. Egbert H. Grandin thought the Society could not be too grateful to Dr. McLean for his conservative paper. The opinions which it expressed were so thoroughly in accord with those which he had always held that he could find absolutely nothing in it to criticise. He had seen, and was still seeing, in a somewhat active gynecological practice, scores of women with uterine and peri-uterine disease, yet he had seen very few whose tubes and ovaries he had been obliged to remove in order to render them comfortable or in some even to effect an absolute cure. He was satisfied that the laparotomy craze which had started from Birmingham a number of years ago had done more harm to womankind than it had done good. He was also satisfied that we had about reached the end of it. So far had it gone that it was not uncommon to hear gentlemen who had but recently been graduated from a medical school boast of having opened forty, fifty, or seventy bellies. He had made it a rule for himself to consider no woman's tubes or ovaries in a condition demanding the knife, with two exceptions, which he presently mentioned. Although on examination he found the uterus adherent, and felt bogginess on either side in the region of the appendages, and the patient in considerable pain, he was still willing to try what could be done by the use of the glycerine tampon, blisters, prolonged hot douches as recommended by Dr. Emmet, mild galvanism, etc. If, after months of persistent treatment of that kind (if he were able to keep her out of the hands of some laparotomist that length of time), he was still unable to make her comfortable, he would be willing and ready to open the abdomen and take out the uterine appendages. But in his experience such treatment was capable, usually, of putting the patient in a condition of comfort. It might not cure her, some physical signs might remain, but if she was comfortable, and might remain so to the end of her life, it was not necessary to tell her that she was still diseased, or to take out her tubes and ovaries to be able to assure her that a radical cure had been effected. The two exceptions alluded to were in cases in which the ovary was really cystic, not simply covered with normal Graafian follicles, and cases of distinct pyosalpinx with the tube behind the uterus, its purulent contents below its uterine extremity, incapable of being drained into the uterus. In those two conditions one should not temporize, but should operate at once, and check progress toward a worse condition. Other treatment than by laparotomy would be likely to do harm, while it could do no good.

In obstetrics he thought physicians were likely to use the forceps too soon; that is, where they were not really indicated. Often where these instruments were applied version would answer a better purpose. The diameters of the pelvis should be carefully measured before resorting to the forceps; if contraction existed, and the head had not engaged, version would prove more conservative than the use of the forceps. But when the cervix had dilated and the head had engaged, if delivery did not take place within half an hour it was his custom to put on the forceps. It spared the woman pain and also the complications to which Dr. Emmet had referred.

Dr. Collyer said he had seen some cases at the dispensary, with symptoms due to dysmenorrhœa, which evidently might have been cured by curetting, and perhaps otherwise treating the endometrium, yet they had fallen into the hands of enthusiastic laparotomists in the beginning of their career and had been subjected to removal of the tubes and ovaries. One case was that of a woman

suffering from dysmenorrhœa, who had retroflexion and some enlargement of the tubes, whether a hydrosalpinx or a pyosalpinx he was unable to say. She consulted many surgeons at their offices, who advised laparotomy, yet she recovered under the use of glycerine tampons, galvanism, and subsequent use of Cutter's pessary. She had then been free from pain two years. He had seen other cases of retroflexion with adhesions, and enlargement of both ovaries and tubes, in which conception and the birth of a healthy child afterward took place. In one of those cases the pyosalpinx originated in a gonorrhœa. In obstetrics he had seen many cases of injurious consequences follow delay in the use of the forceps, and some from misapplication of the forceps, the physician being ignorant even of the kind of presentation.

Dr. H. J. Boldt had been much pleased with the paper of the evening. It recalled to mind one which he had written some time ago, in which he took about the same ground. He held that it was wrong to remove the tubes and ovaries, although the tubes were distended, unless three or four months' treatment failed to produce any benefit, the patient continuing to grow worse rather than better. It was impossible to say at the operating table that the condition present was simply one of catarrhal salpingitis; it could be determined only by a pathological examination. In pyosalpinx a cure could not take place unless the extremity of the tube was patent. It was not right to jeopardize the life of the patient by postponing an operation when one had become convinced that the tube contained pus and was closed. If pathogenic micro-organisms were present in the tube, if the condition were an active one, any delay would subject the patient to the dangers of rupture into the abdominal cavity. As long as pus escaped into the uterine cavity laparotomy should not be done, but he had seldom seen such cases. Where actual tumors of the ovary existed an operation should be done at once; they should never, in his opinion, be punctured through the vagina. He quite agreed with the author regarding the treatment of parametric conditions, such as adhesions with displacement. But there was no one mode of treatment which could be regarded as a panacea for all cases.

Dr. A. P. Dudley said he appreciated the paper, for he believed in conservatism himself, yet he had perhaps operated pretty often for a young man. In the figure of the turning of the tide, he said he thought it was getting full of experience and was moving more slowly. The key-note in the paper really was one of diagnosis and differential diagnosis. He believed he had seen tubes and ovaries removed many times in the past when they should not have been sacrificed. He was not yet convinced that there was nothing in the idea of pelvic cellulitis; that there might not be a swollen condition around the tube while the tube itself remained comparatively healthy, and that conservative treatment would relieve the patient and enable her to bear children. But he felt assured that where pyosalpinx existed, necessarily with some adhesion at the fimbriated extremity to permit the dilatation, the patient would never be likely to conceive. He did not think that the comparison instituted by the author between epididymitis and pyosalpinx was at all applicable to the argument, for the conditions in the two localities were entirely different. In woman adhesive inflammation was likely to take place among organs which would subsequently give rise to most aggravated symptoms. The indications for removal of the tubes and ovaries mentioned by Dr. Grandin were well founded, and the question reduced itself to one of diagnosis and differential diagnosis. An important work for postgraduate schools was to teach men to recognize the condition present. Like Dr. Grandin, he had been thirteen years getting together about seventy-two abdominal sections, and it seemed to him want of conservatism was manifest when quite recent graduates were able to report a larger number. In all his cases, however, he had found sufficient disease to more than warrant the operation. The patients were nearly always first subjected to the treatment described by Dr. Emmet. The author had said that frequently patients were not benefited by the operation, and Dr. Dudley thought one chief reason for that fact was the custom, especially in the past, not to move the bowels for some days after the operation. This allowed adhesions to take place, giving rise to intestinal and other symptoms. He now uniformly moved the bowels within the first twenty-four hours, and refused to give morphine.

Dr. R. A. Murray believed in conservatism in surgery, especially abdominal surgery, but he feared too many had learned to aspire after brilliant results rather than good results unattended by mutilation, when the latter could not be brought about except by patience and labor. Moreover, that which required time was not likely to be submitted to by the patient. Much had been said about laparotomy being done too frequently, but it had certainly taught one important lesson, namely, how best to do it and the little danger which attended it. As Dr. Dudley had said, the key-note to the whole discussion was one of diagnosis. It was very easy to make a mistake in diagnosis in abdominal conditions. Even the most expert had sometimes said they would assert what was in the abdomen after they had opened it, but not before. There might be cases in which that statement was proper, but generally it was quite inexcusable. There was a field for conservatism which had received too little attention, namely, prophylaxis. Many cases in which abdominal section had been made might have been prevented by the correct management of labors and abortions, gonorrhœal inflammations, endometritis, etc. The greatest advance in the future would, he thought, relate to the proper treatment and early cure of acute inflammations before adhesions and chronic conditions resulted. Here much would depend upon the general practitioner, since it was for chronic conditions that patients usually came to the specialist. A radical operation, however, was sometimes in the highest degree conservative, and was indicated in conditions mentioned by Dr. Grandin and other speakers.

Dr. McLean, in closing the discussion, expressed his appreciation of the honor conferred in the presence of Dr. Emmet, and of his remarks, which, as always, were to the point. Nothing in his paper should be construed to mean that he was otherwise than fully in accord with his views regarding the cause and prevention of vesico-vaginal fistula. In general, he quite agreed with the remarks of the other gentlemen, but he would like to ask Dr. Boldt how often he had seen fatal peritonitis from rupture of the tubes. The accident, he believed, occurred so seldom that the fear of it should not be made the excuse for so frequent abdominal section where conservative measures might have spared the tubes and ovaries.

If the conditions of those organs present in many specimens which had been exhibited at the societies in the past demanded their removal, he believed that four-fifths of the women of to-day were fit subjects for ovariotomy. How was it, he would ask, that the accidents to which these women were said to be liable so infrequently occurred in the past when laparotomy was seldom performed?

Dr. Boldt replied to the question, that he had himself operated in four cases for peritonitis due to rupture of a pyosalpinx, and had seen two other cases not operated upon; two years ago he attended an autopsy at the New York Hospital by Dr. Ferguson, who said the fatal peritonitis was due to rupture of a pyosalpinx. He knew also of two or three other cases. With regard to what became of so many of these cases in the past, he said they were called cases of idiopathic peritonitis.

---

There is no time when a hospital manager feels his importance more than when a respectable medical man begs him for his vote to obtain a position on the medical board. Yet every medical man must do it, and every manager's head swells accordingly.

## OUR LONDON LETTER.

(From our Special Correspondent.)

THE ELECTROLYTIC TREATMENT OF URETHRAL STRICTURE —EROSIONS OF THE OS UTERI IN MONKEYS, AND THEIR PATHOLOGICAL RELATIONS TO CANCER IN HUMAN FEMALES—THE RECENT SESSION OF THE GENERAL MEDICAL COUNCIL—DESIRABLE REFORMS IN THE METHODS OF REGISTRATION OF DEATHS—MEDICAL CASES IN THE LAW COURTS.

LONDON, December 7, 1889.

AT the last meeting of the Medical Society of London, a discussion took place on the treatment of urethral stricture by electrolysis. The general tone of the discussion was far from favorable to the electrolytic method. The subject was introduced by Mr. Bruce Clarke, who read a paper in which was embodied his experience of the method for four years and a record of fifty cases. It was extremely necessary, he said, that the surgeon should be master of his apparatus, as electricity was a dangerous remedy in unskilful hands. He argued that the process was not in reality a destructive one, but consisted in modifying and softening the cicatrices by which the strictures were produced; this could be witnessed by anyone who would take the trouble to treat thus a stricture of the urethral orifice. Mr. Bruce Clarke then explained the details of the treatment. He thought some of the cases could not be explained merely on the theory of absorption. He mentioned one case where an ulcer was present and electrolysis produced a rapid cure. Just as a rectal stricture might begin by spasm of the muscular fibres, so urethral stricture could, and often did, begin similarly—an irritable ulcer being the starting-point. Caustic alkali was set free by the negative pole of the battery and cured the ulcer—thus relieving the muscular spasm; if it failed to cure the ulcer, it might, in rare cases, aggravate it and make the stricture worse, and instances of this were narrated. Of the 50 cases of urethral stricture treated by electrolysis, 23 were known to be well after periods varying from one and a half to three years; in 2 cases no relapse had taken place after four years; only 9 were known to have required subsequent treatment.

Mr. Reginald Harrison opened the discussion on Mr. Bruce Clarke's paper, and remarked that he had seen a number of cases which had been submitted to electrolysis in this country and in America, but none of them had increased his regard for the method. The amount of thickening that had taken place in these cases was considerable, but he was not prepared to say whether this was incidental to the stricture or to the treatment employed. He much preferred gradual dilatation, and had had no reason to complain of want of success by this method. Mr. Harry Fenwick observed that in twenty cases in which he had tried the electrolytic treatment they were all considerably worse after the treatment. He considered that the only forms of stricture amenable to electrolysis were those in the deeper part of the urethra associated with spasm. He concluded by quoting the remark of an American practitioner, viz., "that the brilliant results said to have been obtained by electrolysis of stricture depended upon the credulity of the patient and the ingenuousness of the practitioner, or possibly upon some fortuitous act of providence upon which it would not be safe to count." Mr. Lockwood asked Mr. Bruce Clarke whether he adopted the precaution of relieving the more anterior strictures before dealing with those further in. Dr. Routh asked what pole had been used to the stricture. When the electrical current was applied to the uterus, his own experience was that the negative pole dilated the uterus, while the positive tended rather to contract it. Mr. Bruce Clarke then replied. He insisted upon the great attention to technical details which was necessary to insure satisfactory results, and said he was disposed to attribute most of the non-successes to either want of knowledge or want of the requisite attention. The method, moreover, was only applicable to certain cases. He would have been glad to know how far these strictures began as spasmodic strictures. He always used the negative pole with a strength of from five to ten milliampères.

A research which promises to have important results was brought before the Pathological Society at their last meeting. Messrs. Bland Sulton and Gordon Brodie (who made the communication) said that they had for some time been accumulating material for an investigation of cancer, especially in connection with the uterus. It appeared that uterine cancer, though so common in the human female, was rarely met with in other mammals. This induced them to study the cervix uteri in monkeys. Menstruation in monkeys was carefully studied. Last summer a macaque was particularly watched. It suffered from leucorrhœa and menorrhagia so profuse as to render it unfit for exhibition. Being of small value, it was killed. The uterus was found to be acutely retroflexed; the cervix was enlarged, the os patulous, and a florid-looking mass projected from the os identical in appearance with what was termed in gynecology an erosion. Sections of the parts were examined microscopically, and under a low power the mass protruding from the os, as well as a polypoid mass some distance up the canal, resembled a cervical adenoma, and appeared to be identical in structure with the glandular tissue held to be characteristic of erosions in women, the acini being apparently lined by columnar epithelium. Many of the most typical acini were filled with a singular, apparently homogeneous, material. Under higher powers and careful illumination the supposed columnar cells were seen to be club-shaped, and in favorable sections the supposed glandular crypts turned out to be rosettes fringed with the clubs so characteristic of actinomyces. The clubs varied somewhat in shape. Many of them fringed the rosettes with the greatest regularity; in other places they occurred in "banana-like" bunches, especially when stained with fuchsin. The clubs surrounding the rosettes stained with difficulty. In some places a cluster of clubs had been cut transversely; in such, a characteristic mosaic was produced. They could not detect the filaments, but this was probably due to their lack of skill in staining methods, but a number of granular bodies presented themselves in various parts of the section. Thus far the microscopic characters were consonant with actinomycosis. On examining the centre of the rosettes, some distinctly rounded bodies caught the eye, associated with clumps of epithelioid-looking cells; when these central bodies were critically examined they resolved into cysticerci with the head and neck retracted. Whether their presence in the midst of the rosettes was accidental or otherwise, would require further elucidation; so far as they had examined the sections, the cysticerci appeared to have some causative relation to the rosettes. Messrs. Sutton and Brodie stated in their communication that, although they wished at first to limit this preliminary statement to facts connected with monkeys, they could not refrain from observing that they had detected, so far as the rosettes and clubs were concerned, exactly analogous conditions in erosions from the human cervix uteri, and in a case of cancer of the cervix. They further found that Dr. John Williams, in one of the plates illustrating his "Lectures on Cancer," had depicted, as appearing under a high power, cancer cells, but they found these columnar cells identical with their clubs, and the peculiar clump of cells in the drawing was identical with those seen in the monkeys in association with the cysticerci. Again, in the beautiful plates in vol. xxxii. of the Pathological Society's Transactions, they found that Mr. Harrison Cripps had accurately delineated clubs and rosettes under the name of adenoid cancer of the rectum. Many of his exquisite drawings represented the microscopical characters of the lesions in their monkeys, and in the erosions of women. They deemed it right to men-

tion these things to show how wide a field was opened up.

I referred some time ago to the conduct of the Medical Battery Company in relation to the Zauder Institution purchased by them. The vagaries of the so-called Medical Battery Company have engaged the attention of the Medical Council at their recent session, with the result that the medical officer of the company (Mr. Leeson) has had his name struck off the Medical Register for having acted as a "cover" to Mr. Harness, who represented himself as the consulting medical electrician to the Company, but who, it was alleged, practised as if he were a duly qualified medical man. Within the last year or two the Council has displayed unusual activity in dealing with various irregularities, and especially in regard to the "covering" of unqualified men by legally qualified practitioners. At their recent session, however, they sanctioned the restoration of two names to the Register which had been expunged therefrom. Among the subjects discussed at the Council's session was the registration of midwives and of trained nurses; but perhaps one of the most important subjects brought before the Council was in regard to the present system of the registration of deaths. Dr. Glover brought forward a motion to the effect that the Government be requested to issue annually to every registrar of births and deaths a copy of the Medical Register, so that the registrar could ascertain whether the person certifying the cause of death was a registered medical practitioner. This motion was agreed to, as was also another brought forward by Dr. Glover, which was to the effect that the Registrar-General be memorialized by the Council to cause the forms of certificates of the cause of death to be numbered, and to instruct registrars, in issuing them to applicants, to ascertain that the latter were registered practitioners, and to keep a record of the number of certificates given to each applicant.

Two cases of interest to the profession have just been decided in the law courts. In the one, a medical practitioner, sued for damages for the alleged wrongful giving of a certificate in lunacy, was able to stay proceedings under a clause of the new Lunacy Act, and thus avoid enormous trouble and expense. The other case was one in which a provincial parish doctor sued a local newspaper for libel, for having attributed to him heartless conduct for refusing to see a child without an order from the relieving officer. Evidence was given that the position of the mother was not that of a pauper. The jury awarded the doctor twenty pounds damages.

## CIVIL SERVICE EXAMINATIONS FOR PHYSICIANS.

To the Editor of The Medical Record.

SIR: In Dr. Dawbarn's letter to THE MEDICAL RECORD of December 7th, the following sentence occurs:

"The first Civil Service examination for permanent positions for medical men, ever held in New York, I believe, was that of February 3 and 4, 1885."

The first held was in October, 1884, as will be seen from the following quotations from the Annual Report for 1884 of the Hudson River State Hospital for the Insane. These quotations further show that whatever may be the iniquities practised by the political managers of such examinations in the cities of this State, the methods of the State Civil Service Commission at that date, both as regards appointments of examiners and fairness of dealing were above reproach:

"The competitive examination was held at the Academy of Medicine, in the city of New York, beginning October 20, 1884. The Examining Board was constituted as follows: Dr. Stephen Smith, State Commissioner in Lunacy, Chairman; General Silas W. Burt, Chief Examiner of the Civil Service Commission, conducted the personal examination of the candidates; Professor Henry Drisler, of Columbia College, prepared the examination paper on General Education; Drs. James R. Leaming and Darwin E. Hudson that on General Medicine; Dr. Allan McLane Hamilton that on the Anatomy, Physiology, and Pathology of the Nervous System; Dr. Theodore H. Kellogg that on Insanity; Dr. A. N. Bell that on Preventive Medicine; Dr. Stephen Smith, for Dr. Lewis Balch, that on Surgery; Dr. A. E. MacDonald that on Hospital Administration."

"Soon after the conclusion of the examination a communication, dated October 28th, was received from General Burt, Chief Examiner, as follows: 'I had hoped to give some definite intelligence concerning the recent examination before this, but we have to await the convenience of the examiners, who are physicians in large practice and cannot be hurried. Of the sixteen applicants there appeared thirteen, and of these only eleven went through the whole examination, which occupied three days, the greater part of the last one being devoted to a personal test of the applicants at Ward's Island Asylum, by Dr. MacDonald. I inclose a set of all the papers used, except a short one by Dr. MacDonald, at Ward's Island. I think the examination was rigid, and, as the first effort of the kind, will be very satisfactory. Dr. Smith thinks that at least two will be of superior standing. I will acquaint you with the result as soon as all the examination papers are marked and reported.' Under date of November 13th, Mr. Clarence B. Angle, Secretary of Civil Service Commission, writes to Colonel Amasa J. Parker, Jr., President of the Board of Managers: 'I have the honor to transmit herewith a certificate of the candidates on file as eligible to the position of first assistant physician in your institution. I also inclose a statement of the standing of such candidates upon the several obligatory and optional subjects of examination, and also their original application papers. Should your honorable body desire any other information on file with the commission, I shall take pleasure in responding to your requests.' The *minutes*, as furnished by General Burt, of competitive examination for the position of first assistant physician in the Hudson River State Hospital, giving the standings on the several subjects of the two competitors who passed above the minimum standing, show the highest markings to be for Dr. Frederick Peterson, of Buffalo, N. Y. Dr. Peterson's markings are as follows: *Obligatory subjects:* General Education, 86; General Medicine, 92; Physiology, Anatomy, and Pathology of the Nervous System, 100; Insanity, 75; Preventive Medicine, 75; Surgery, 85; Administrative, 62. *Optional subjects:* Microscopy, 100; Latin, 60; German, 91; Swedish, 70; Translation from French, 70. The relative weights given to the obligatory subjects respectively were the following: General Education, 3; General Medicine, 3; Anatomy, Physiology, and Pathology of the Nervous System, 4; Insanity, 5; Surgery, 2; Administrative, 3; total, 20. The standing of a candidate is reached by the following method: The marking of every examination paper is multiplied by the given weight of the corresponding subject. The results are added and the product divided by the sum-total of the weights. The quotient gives the average standing on the whole examination. The standing of Dr. Peterson was 82.20."

As a result of this examination I was appointed permanently to the position (resigning January 1, 1888). For some months before October, 1884, the competitive examination was advertised extensively in several New York daily papers and in THE MEDICAL RECORD. At the time of the examination I did not know who the examiners were, nor had I any acquaintance with any manager or officer of the Hudson River State Hospital, or any political influence whatever. I was deeply impressed with the perfect equity in the conduction of the whole affair. Besides the above quotations, the Annual Report referred to published also the whole series of examination papers. This was Civil Service appointment in the highest sense of the term. Very truly yours,

FREDERICK PETERSON, M.D.

201 WEST FIFTY-FOURTH STREET.

To the Editor of the Medical Record.

Sir: My attention has been called to the following paragraph, clipped from your issue of December 7, 1889:

"... Dr. A B C, a former student of mine, did not, until after the fact, hear of the examination held this summer for the 'Summer Corps' of physicians to assist the regular corps of the Board of Health. He was but a day or two late, and determined to try political influence. In this he was successful, *for a well-known city official, of his own language and religious belief, procured for him a copy of the questions, which he answered at his leisure at home, and doubtless to his own satisfaction.* His paper was then duly handed to his political friend, was slipped in among the other papers, and in a short time he received his appointment as a member of the 'Summer Corps,' in which he remained throughout the season. . . . .

(Signed) "Robert H. M. Dawbarn, M.D.

"345 West Fifty-sixth Street, New York."

Will you kindly permit me space to characterize this statement as utterly false.

Respectfully yours,

G. K. Ackerman,

*Secretary and Executive Officer.*

New York City Civil Service Boards, Cooper Union, New York, December 16, 1889.

## HOW TO PREVENT AN EPILEPTIC WHO FALLS IN THE STREET FROM BEING COMMITTED AS A DRUNKARD.

To the Editor of The Medical Record.

Sir: John Wiesler, 606 East Fourteenth Street, an inoffensive, sober, poor workingman, is epileptic.

Twice he happened to have an attack of his disease in the street; each time he was arrested, and, on the erroneous charge of drunkenness, first fined ten dollars, the last time sent to Blackwell's Island for ten days. He served this term from September 4, to September 14, 1889.

Punishment for epilepsy!

The man speaks German only, and had certainly no opportunity to explain himself or to communicate with his wife and child while he was under sentence.

I have learned that the experience of John Wiesler is also the experience of other epileptics of this city.

This rough handling of an unfortunate by a policeman, and the punishment inflicted by a police justice, reminds us of some of the customs of the middle ages.

From what I have seen myself, and what has been seen by others with whom I spoke on the subject, it appears that some policemen, when they find a person unconscious on the street, never think for a moment that there could possibly be any other cause of unconsciousness but drunkenness.

This should be remedied; there should exist precautions against such revolting errors of police and police justices, and, I think, above all, it is each and every physician's duty to assist in finding means to that purpose.

I wish to suggest that medals should be distributed, to be worn by epileptics; these medals should be familiar to every policeman; there should be a certain mode of attachment and a certain part of the body where they would have to be looked for (for instance they might be attached to a rubber band around the neck—like the checks of valuables in the surf-baths), and by means of these medals policemen would be enabled to distinguish an unconscious epileptic from a drunkard.

In bringing the case of John Wiesler, through your columns, before the medical profession, I hope the crying wrong described will be noticed and acted upon by some of our societies, for instance the Medico-Legal Society.

A. Rose, M.D.

208 Second Avenue, New York.

The Vanderbilt clinic is as bitterly complained of by practitioners on the west side of town, for treating patients who are able to pay, as is the Presbyterian clinic on the east side.

# Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 8 to December 14, 1889.*

Hall, John D., Major and Surgeon. Leave of absence granted for ten days, to take effect upon being relieved from duty at Fort Niagara, N. Y. Par. 4, S. O. 285, A. G. O., Washington, December 7, 1889.

Carter, Edward C., Captain and Assistant Surgeon. By direction of the Secretary of War, will be relieved from duty at Willet's Point, N. Y., upon the arrival at that station of Major Clarence Ewen, Surgeon, and will then proceed to Fort Walla Walla, Wash., and report in person to the commanding officer of that post for duty, reporting also by letter to the commanding general, Department of the Columbia.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending December 14, 1889.*

Ross, J. W., Surgeon. Detached from Navy Yard, Pensacola, Fla., and placed on waiting orders.

Kite, I. W., Assistant Surgeon. Detached from Naval Hospital, Philadelphia, Pa., and to Navy Yard, Pensacola, Fla.

Rogers, B. F., Surgeon. Ordered to special duty at Norfolk, Va.

Leach, Philip, Passed Assistant Surgeon. Ordered to duty at Naval Academy, Annapolis, Md.

# Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 14, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 21 | 7 |
| Scarlet fever | 71 | 5 |
| Cerebro-spinal meningitis | 2 | 3 |
| Measles | 55 | 3 |
| Diphtheria | 118 | 28 |
| Small-pox | 0 | 0 |
| Variola | 1 | 0 |
| Pertussis | 0 | 0 |

Cooling the Body by Spray.—Dr. S. Placzek, following up some laboratory experiments by Preyer and Flashaar, on the effect of spraying a considerable part of the body surface of animals with cold water, has applied the spray for the purpose of reducing febrile temperature in human beings. In the case of a man suffering from phthisis, whose temperature was high, he found that by spraying about a pint of water at between 60° and 70° F. over his body, the temperature fell to normal, and continued so for several hours. Again, a similar method was satisfactorily applied in the case of a girl with diphtheria. In the healthy human subject the spray lowered the temperature nearly 2°, and in animals which had been put into a condition of septic pyrexia by injections of bacteria, the temperature was reduced to normal by the spray.—*Lancet.*

Preventive Inoculation for Yellow Fever.—The following report was presented to the Academy of Sciences, France, by Dr. Domingos Freire, Professor of Organic Chemistry and Biology in the Faculty of Medicine of Rio de Janeiro, Brazil: "The epidemic of yellow fever that developed in Rio de Janeiro in 1888 and 1889,

and which propagated itself in several other places in the interior of Brazil, has been the means of demonstrating for the fourth time the value of inoculations by means of the attenuated microbe of yellow fever. The maximum of the epidemic was between the months of December and March, the first sporadic cases having appeared about the end of the month of May, 1888, and the last in June, 1889. During this period there were inoculated 3,570 people, to wit, 988 strangers and 2,582 Brazilians, divided thus: The city of Rio, 2,138; city of Campinas, 651; town of Vassouras, 199; city of Nicteroy, 166; city of Santos, 133; Desengano, a village of 425 inhabitants, 102; Serraria, a small town, 80; city of Rezende, 54; Cataguazes, a village of 2,000 inhabitants, 50. The disease swept with great intensity in all of these spots, and the vaccinations were made, for the most part, during the height of the epidemic. Of the 2,582 Brazilians, there were 1,740 that should be added to the 988 strangers, as this figure embraces not only individuals coming from the interior and resident in the city of Rio for less than six years—that is to say, non-acclimated—but also children, who, according to our experience, are just as susceptible as the strangers themselves. The rate per hundred of mortality among the vaccinated was 0 078; at Santos, at Rezende, at Serraria, and at Cataguazes, the immunity from the disease was absolute. Here is the rate per cent. from each locality: Rio, 0.98; Campinas, 0.46; Vassouras, 0.05; Nicteroy, 0.75; Santos, 0.00; Desengano, 0.09; Serraria, 0.00; Rezende, 0.00; Cataguazes, 0.00. The mortality from yellow fever among the non-vaccinated was 4,135, divided thus: City of Rio de Janeiro, 2,407 (this includes the dead from the Marine Hospital); Campinas, 812; Vassouras, 15; Nicteroy, 177; Santos, 650; Desengano, 221; Serraria, 21; Rezende, 11; Cataguazes, 20. Among the 4,135 there were about 2,800 strangers, of whom 1,176 died in Rio (and 750 of these in the Marine Hospital), 63 at Nicteroy, 500 (about) at Santos, 300 (about) at Campinas, 7 at Desengano, 3 at Rezende, 3 at Vassouras. Thus one-fourth of the deaths were among Brazilians who were unaccustomed to the poison, inasmuch as they resided in localities where the epidemic appeared for the first time this year. In order to make the efficacy of the inoculations more marked, it suffices to remember the proportion established by M. Jemble in Senegal, to wit, that among the strangers who had been there from one to three years, 75 per 100 were attacked by yellow fever, and 68.06 per hundred died. Applying these facts to the vaccinated strangers, or the provincials who had from a few days to three years' residence in the infected locality, we obtain the following results: At Rio we vaccinated 1,183 people under the above conditions, of whom at least 591 should have succumbed to the disease, but only 18 died. Thus 573 lives were saved. At Campinas, a city that never before had an epidemic of yellow fever, and where the 651 inoculated might be considered as new arrivals, of whom 325 should have died, the unsuccessful inoculations were but 3. At Vassouras, 5 should have died; one only died, who was not a recent arrival. At Nicteroy the 11 strangers, under the conditions cited above, should have furnished five deaths; one only was a victim. At Santos, of 57 persons under the same conditions, 28 should have died, but the immunity from disease was absolute. At Desengano, the two unsuccessful inoculations were among strangers who had lived from six to eight years in the country. But in view of the fact that the disease obtained for the first time, all of the 102 persons inoculated were as susceptible as strangers who had just arrived. Among them 51 should have died. At Serraria, according to the main calculation, 39 should have died, whereas the immunity from the disease was absolute. The same reflections apply to Rezende, where the 54 vaccinated should have furnished 27 deaths, and at Cataguazes, where the 50 vaccinated should have furnished 25 deaths, in view of the fact that the epidemic made its first appearance in these two localities; still the immunity was perfect, without exception.

"*General Résumé.*—We have vaccinated, since 1883 to 1889, 10,524 people, with a mortality of 0.04 per hundred.

| | | |
|---|---|---|
| Vaccinations made in | 1883–84 | 418 |
| " " | 1884–85 | 3,051 |
| " " | 1885–86 | 3,473 |
| " " | 1888–89 | 3,582 |
| | | 10,524 |

"I had to cease vaccinating in 1887, owing to my trip to Europe and in the United States. The mortality from yellow fever among the non-vaccinated, during the four epidemics mentioned above, was close on to seven thousand. Let us add, in closing, that all the results given have been authenticated by a large number of medical men, and municipal and police authorities. The vaccinations were made without fee. This succinct statement proves, without question, the truth of all the doctrines founded by our eminent master, M. Pasteur."

DIAGNOSIS OF CEREBRO-SPINAL MENINGITIS BY PUNCTURE OF THE LIVER.—Dr. C. Bozzolo reports a case of cerebro-spinal meningitis, in which the diagnosis was assisted by bacteriological observations made on the fluid obtained by puncturing the liver. A man, aged fifty-four, who had been ill for five days previously, was admitted into the clinic at Turin suffering from feverishness, pain in the right side of the neck, jaundice, enlargement of the spleen, painful enlargement of the liver, bronchitis, and albuminuria. A rigor occurred more than once. Except the pain in the neck and vomiting, no symptom whatever of meningitis existed. Six days after admission the patient died, having been slightly delirious for the previous forty-eight hours. Diagnosis being difficult, the author had on the fourth day after admission made an exploratory puncture of the liver, which was still painful. The blood extracted showed by cultivation and after experiments on animals the existence in it of Fraenkel's diplococcus of pneumonia. This result, in the absence of pneumonic and pleuritic symptoms, with the existing pains in the neck and vomiting, encouraged Bozzolo to diagnose meningitis, a diagnosis which was confirmed by the post-mortem examination. In addition to the morbid changes in the meninges, gall-stones and acute endocarditis were found.—*Lancet.*

ANTIPYRIN HABIT.—To the already long list of drugs, the use of which, under proper restrictions, is both beneficial and proper in combating the various ills to which flesh is heir, but whose abuse becomes a curse to humanity, another has recently been added. Scarcely have we learned to properly use antipyrin than the tocsin of alarm must be sounded against its abuse. The recent discovery of its value as a nerve-tonic places it on the list with morphine, chloral, cocaine, etc., so seductive is its gentle, soothing influence upon the overstrained nerves. Its victims are already found, especially among society women, whose nerves, strung up to a high pitch by the overwhelming demands of a winter season of gayety, seize eagerly upon anything that will afford relief from the headaches and other disorders arising from prolonged fatigue and overtired nerves. So pleasing is the effect that it is soon used for every trifling ill feeling, until the patient finds herself unable to live without it, and the fascinating "antipyrin-habit" is formed. Properly used as a nerve-tonic, its effects are admirable, but *abused*, the victim becomes even more hopelessly entangled than the morphine or cocaine victim. The effects vary with the dose. In large doses it produces complete relaxation with loss of reflex action. In moderate doses, continued, it induces convulsions. As a stimulant its effect is much like that of quinine.—*International Dental Journal.*

THE AMERICAN ACADEMY OF MEDICINE has so amended its constitution as to permit the Academy to admit as members those of the profession who have pursued courses of study calling for an equivalent of mental training to that necessitated in the securing the degree of A.B.

### CARDIAC THERAPEUTICS.[1]

BY JOSEPH M. PATTON, M.D.,

CHICAGO, ILL.

DIVIDING diseases of the heart into those which are acute in their course, and are accompanied by the usual manifestations of acute diseases, and those which are slow in development and chronic in nature, and which are, as a rule, secondary to some acute condition, we have in the latter those which demand most often our attention, both as to diagnostic ability and therapeutic skill. It is to the latter that I wish to call your attention, and as the orifices of the left heart enjoy almost a monopoly of the diseases so catalogued, it will facilitate matters to consider, in turn, the conditions which may present through disease of the aortic and mitral valves and their therapeutics.

An intelligent consideration of the treatment of these conditions implies a concomitant study of the pathological condition involved, as without a knowledge of the pathological changes, and the sequence of their production, the scientific application of the more important remedies cannot be made.

The affections of the aortic valve appear later in life, as a rule, than those of the mitral; the latter are more often due to endocarditis, while aortic disease is generally due to atheroma, arterio-sclerosis, and like conditions giving rise to changes in the aortic ring and valves.

Stenosis of the aortic semilunar valves is the most favorable of all valvular lesions, from a prognostic standpoint. It may exist for years without the necessity of medicinal aid, at least so far as the heart itself is concerned; the simple hypertrophy of the ventricle relieves the condition, and until this becomes excentric the heart is not in need of aid so far as its pumping powers are concerned.

With insufficience of the valve it is different; the hypertrophy here is excentric from the beginning, and while cases are recorded where regurgitation alone, or in connection with stenosis, existed for years in laboring men without serious difficulty, still rupture of compensation occurs quicker in insufficience, because of the constant intra-ventricular pressure during diastole caused by the additional stream of blood.

There are, however, symptoms occurring during the period of compensation, or hypersystolic state of Fernet and Huchard, which will demand relief. These symptoms are common to both conditions, but are generally more marked in regurgitation, because of the dilatation of the aorta which obtains through the larger volume of blood discharged, and the greater force given it because of the immense hypertrophy which develops in regurgitation.

Retardation of the circulation is effected in both instances. In stenosis the arteries are scantily filled, anæmia of the brain develops on slight exertion, syncope, fainting, dizziness, palpitation from nervous excitement.

In regurgitation the pulse is bounding, a high-up stroke with absence of the dicrotic wave, a pointed summit, voluminous but maybe weak and irregular on slight exertion, the so-called Bellingham or Corrigan pulse. Passive hyperæmia of the brain and aortic system, dizziness, ringing in the ears, cyanosis, pain under sternum, along clavicle, and down the left arm, due, according to Peter, to inflammation of the cardiac plexus. Angina pectoris may occur. Loss of mental power, insomnia, or even insanity, may result from the condition of the cerebral circulation, as cerebral activity is in close relation to the condition of the circulation, as has been shown by Bernard and Mosso.

Patients with cardiopathies of this class with a rheumatic origin do well on the iodide of potash combined with the bicarbonate of potash, and generally take it indefinitely without trouble. Iron, attention to the nutrition, moderate exercise are necessary. Dujardin-Beaumetz relies on opium for the relief of cerebral anæmia and dyspnœa. Gubler states that the action of opium is due to the congestion it produces. Picard and Reathi think it acts on the cardiac ganglia, as its effect is manifest on the heart after section of the vagi. The relief afforded by other vascular dilators would correspond with the former theory. The cerebral symptoms would appear to result from lack of blood-supply through passive congestion, both in stenosis and regurgitation, and by vascular dilatation the blood-pressure is lowered and the heart, for the time being, keeps up the supply. The dyspnœa may be relieved in the same way, or by sedation of the cardiac plexus. Subcutaneous injection is the method recommended, but there are objections to this, unless it be in acute conditions like angina pectoris.

Nitrite of amyl by inhalation is useful as a vaso dilator, but its effects are very transient. Tri-nitrine, three to four drops of a one per cent. solution, or by hypodermic use, may be used in true or pseudo anginas.

Antipyrin has appeared as a remedy for angina pectoris, as it has for most everything else. Eloy says it is to be avoided in true angina, because of its injurious effect on the heart muscle, and because of the danger of dilatation. On the contrary, Professor Sée says it is perfectly safe, and very efficient in gramme doses, one hour apart, till four or five grammes are given, or in hypodermic injection half a gramme in distilled water, with none of the unpleasant after-effects produced by the hypodermic use of morphia.

Galvanism is of benefit in some cases of neuralgia or angina of cardiac origin.

For the paroxysmal dyspnœa and cardiac asthma bromide of potash is useful; cicutine, the alkaloid of conium maculatum, is also recommended. In the hypersystolic condition, with increased vascular tension, aconite is a valuable remedy; two drops of the tincture every three or four hours, followed by one drop three or four times a day, will give marked results in many instances.

With the occurrence of degeneration and rupture of compensation the demand for aid to the heart comes, while mitral disease is in many instances but a sequence of aortic trouble. Some writers would indicate that this condition, called by Fernet and Huchard the hyposystolic state, develops only when mitral disease has been added, and apply, therefore, the true cardiac tonics only to conditions resulting from mitral disease. Franck and Deborde claim that dilatation and hypertrophy of the left auricle is the factor in compensating aortic regurgitation, the blood being discharged into the ventricle with sufficient force to overcome the pressure in the ventricle. This assumes that it is necessary to have the above con-

[1] Read before the Chicago Pathological Society, October 15, 1889.

dition of the auricle in order to obtain compensation in aortic regurgitation; this I do not believe. As the auricular contraction takes place before the ventricular, I do not see how it can aid in compensating the ventricular dilatation. I believe that with the production of mitral regurgitation and auricular dilatation and hypertrophy, you have the beginning of the end. Objections have been made to the use of heart tonics in aortic stenosis, because they prolonged the systole; this is the effect desired. By prolonging the systole and increasing the force you get more blood through and postpone the development of an asystolic condition, and in regurgitation you enable the ventricle to empty itself and obtain the same result.

Cardiataxia may render the administration of these remedies necessary in aortic lesions uncomplicated by mitral disease, but the passive congestions which demonstrate heart-failure in mitral lesions are wanting, and while the indications for their use are the same, the necessity is not present to as great an extent.

I cannot accept the statement of some writers, that stenosis and regurgitation of the mitral orifice never occur separately; it is true that to stenosis is added insufficience, but stenosis may exist single for a long time. Regurgitation may exist indefinitely and cause death by cardiac failure without being complicated by stenosis. In stenosis auricular hypertrophy compensates and there will be little trouble except on exertion, where the rapid heart's action does not give the auricle time to empty itself. The auricle may succeed in freeing itself of blood with slow heart's action, and thus the pressure in the pulmonary circulation is not so constant as in regurgitation. In either instance, when the mitral valve is primarily affected, the compensation effected by the right heart obviates medicinal treatment until failure occurs. The systemic circulation calls on the left heart and moderate hypertrophy results; when mitral disease is secondary to aortic lesion it comes with compensatory failure, and the relief you can furnish is in inverse ratio to the amount of fatty granulo degeneration of the muscle-fibre.

In compensated conditions there are various rules to be followed, which are of more utility, when observed in time, than therapeutic measures; they apply alike to all conditions of compensated heart lesions. Out-of-door exercise should be had in moderation, all active exertions should be interdicted. Mountain-climbing has not been as well supported as might have been expected from the claims of its originator; it is no doubt of use when properly and carefully observed, but any exclusive method of training would probably result in harm in many cases. All professions and occupations entailing exposure and fatigue should be avoided. The diet should be nourishing and strengthening, the days of restricted diet for the limitation of hypertrophy are past.

All alcoholic drinks should be strictly forbidden. Tea and coffee sparingly or not at all. Tobacco should be absolutely forbidden. The most desirable climate is one of steady, uniform temperature, moderate, with a dry atmosphere, with an elevation of not over two thousand five hundred feet.

Baths of compressed air have been recommended by Lambert and Waldenberg, as a means of relieving the work on the heart; Ducrocq and Fontaine maintain that they are useless, or even deleterious.

An interesting question arises in relation to pregnancy and the cardiopathic state. Women with organic disease of the heart should seriously consider the question of marriage. The altered condition of the blood in the pregnant state and extra demand on the heart cause hypertrophy. In the normal heart this disappears after accouchement, but organic disease may be seriously aggravated. These patients are especially liable to miscarriage.[1]

In relation to abortion, mitral regurgitation is said to be most dangerous; the least dangerous is aortic regurgitation. Mitral constriction is less dangerous, as far as labor is concerned, than regurgitation, according to Sée.

Mothers suffering from cardiac lesions should not be allowed to nurse their children.

The medicinal treatment of the compensated state is nutritive tonics at the earliest sign of failure, with perhaps some of the sedative bromide in cases exhibiting a nervous temperament. Bromide of potash is the favorite salt; in many cases better results can be obtained from the bromide of sodium; the principal medicines to be used here are iron, quinine, strychnia, and arsenic. Lockie considers the latter a cardiac stimulant. The objection is made against iron, that its tendency to produce congestions should prohibit its employment; I do not believe it does injury in this way, and think the period of compensation may be much prolonged by its use. I employ a fresh carbonate of iron pill, or the tincture of the citromuriate with tincture of cinchona.

Attention to the state of the stomach and abdominal viscera is always an important element in treatment; the connection between the cardiac ganglia and the abdominal sympathetic ganglia, through the nerves of cyon and other connections, readily explains the effect on the heart of disturbances of the abdominal viscera.

Notwithstanding our efforts in these various directions, the time comes when something further must be done. In many instances the patient presents himself for the first time for the relief of symptoms occurring as a sequence to failure of compensation. Degeneration of the muscular fibre reduces the integrity of the muscle, and prevents it from longer resisting the blood-pressure, transforms simple hypertrophy into excentric, or in excentric hypertrophy allows of the extension of dilatation. This diminishes the pumping power of the heart, and gives rise to a series of symptoms indicative of the necessity for heart tonics.

The heart's action becomes labored on slight exertion, dyspnœa with slight cough, slight swelling of the feet and ankles at night, evidences of gastro-intestinal catarrh; on examination you find the action of the heart out of proportion to the tension of the vessels and condition of the circulation; the muscular element of the first sound is not clear and distinct, later on œdema at the base of the lungs develops. These symptoms, in a heart where compensation has sufficed for the requirements of the circulation, admonish you that the time has arrived for the employment of remedies which heretofore have been contra-indicated.

First, by right of seniority, is digitalis, this time-honored remedy still maintains its place at the head of the list of cardiac tonics. Withering employed it in the Birmingham hospital in 1775, and in 1785 published a work on it. Contradictory opinions have been given from time to time in regard to its action, but to-day all observers who have placed themselves under similar conditions of observation, agree pretty closely as to its action. Moderate doses slow the pulsations, increase their force, fulness, and regularity; the vascular tension is increased, as shown by Chauveau, Marcy, Siredy, Legroux, Gubler, and others through sphygmographic tracings, also by Briquet's hæmodynamometer. According to Sée, digitalis slows the heart by exciting the cardiac inhibitory nerves and ganglion, as the action is omitted if the vagi be cut. According to Cavazinini there is little action on the auricles, the ventricular tone is increased, with a secondary action on the vessels. Gubler, who has made extensive observations, says there is first a slowing of heart's action, doses too long continued produce irregular, intermittent heart's action, and cardiac exhaustion from prolonged stimulation. The best effects are obtained after some days of administration, and may remain some time after ceasing the drug. The chemistry of the drug has developed a so-called alkaloid, digitaline, which is rather a glucoside than an alkaloid, besides other principles and extractives.[1]

[1] Durosier reports 21 abortions or premature births in 41 cases. Out of 40 births from cardiopathic mothers, 37 died before six years.

[1] The amorphous digitaline of Quivenne and Homolle is extracted from the leaves, the German digitaline from the seeds. The digi-

The lack of definite chemical data in regard to these substances is a serious bar to their therapeutic employment. Digitaline may be used hypodermically. Gubler claims good results, using a five per cent. solution of amorphous digitaline in alcohol and water, and injecting about one milligramme. Powdered digitalis is not reliable; the tincture is the best form for action on the heart, the infusion when stimulation of the kidneys is desired. The particular valvular lesion originating the trouble is of little import in determining the necessity for its use; the comparative amount of hypertrophy and dilatation, and the integrity of the muscular fibre, are the conditions which determine the indications or contra-indications for its employment. Fatty heart, or granulo-fatty degeneration of the muscle fibre, are positive contra-indications, where the majority of the fibres have been subjected to this change.

Dujardin-Beaumetz says the failure of the drug to act in these cases constitutes a therapeutic test, and relates a hospital case in which it failed utterly and death resulted. The question naturally arises as to how much the digitalis had to do with the period at which the fatal result was attained.

It is certainly better to depend on our diagnosis of degeneration for contra-indication, than on experimental evidence obtained at the risk of the patient's life.

When degeneration is in excess, a veritable digitalis asystolia may result from its use. Moreover, the action of the drug in contracting the vessels throws more work on the heart, while no additional pumping force is furnished the organ.

James Stewart recommends for serious heart-failure rest in bed, forbids liquids, full doses of digitalis; if good results follow, diuresis is increased; if the amount of urine falls after increase by digitalis, the drug should be stopped; he gives forty minims of tincture four times daily during three days, but as much as half an ounce may be necessary.

According to Huchard, digitalis is of benefit in transitory asystole with venous stasis from asthenic conditions of vessels and heart muscle. Useless in compensated state. Harmful in hypertrophy with increased arterial tension, and in permanent asystole with embarrassed circulation, and irremedial fibroid changes of cardiac muscle. Cardiac arythmia to be treated by digitalis if due to valvular lesion; if due to myopathic, reflex, toxic, or nervous origin, is useless.

Stücker recommends ergot with digitalis in diminished arterial tension, aortic insufficiency, idiopathic dilatation, certain stages of arterio-sclerosis, and sometimes after violent bodily exertion. With increased arterial tension, as in chronic nephritis, with rapid and irregular heart's action, digitalis may not be safe, alone; lower the vascular tension with nitro-glycerine, or other nitrites; he thinks caffein may be better in such cases.

The combination of vascular dilators with cardiac tonics, has not received the experimental attention which so promising a theory deserves; it is recommended by Stücker, Da Costa, and others. The ideal cardiac tonic may yet be obtained, and the most efficient aid rendered the heart by this means.

It does not seem to me that the cumulative effects of digitalis, about which so much has been said, need interfere with its administration as much as has been claimed. If the case is a proper one for the drug, and the dose properly managed, it will seldom interfere in this manner. In most cases it is better to interrupt the administration for a few days every ten days.

The most serious trouble will be encountered through its irritating action on the intestinal tract, which in some instances will effectually prohibit its employment; recourse may then be had to some other drug of the same class, and the principal one of these is strophanthus.

taline of Nativelle is similar chemically to the amorphous, but much more powerful. Roucher's digitaline-globular resembles the amorphous. The German of Hosmann and Merck is less powerful than the amorphous.

Professor Fraser, of Edinburgh, furnished a journal article on strophanthus in 1885; the active principle he claimed to be strophanthin, its action on the heart in the frog similar to digitalis, but more powerful. The chief therapeutic difference being its failure to contract the blood-vessels.[1]

Various results have been obtained by other observers. Popper, through experiments on dogs, concludes that it increases arterial pressure by action on the heart, as it occurs if vaso-motor paralysis be previously produced, increased venous pressure is not constant, the vagi may be paralyzed, but the accelerator nerve remains intact.[2]

Whatever may be the direct method of its action, it is undoubtedly a useful cardiac tonic. I have used it in quite a number of cases, and while I am not prepared to rank it with digitalis, when the latter can be properly administered, I have not had any distinct failures with it, and have had much satisfaction in its use in cases which were not suited to digitalis.

One patient, a wood-turner by occupation, suffering from mitral stenosis, to which was subsequently added insufficiency with a dilated and hypertrophied auricle, with rapid and very irregular heart's action, was totally unable to take digitalis from gastric intolerance; it also seemed to increase the irregularity. At favorable times the auricular and ventricular contraction could be distinctly separated; on the slightest exertion the heart became irregular, with marked throbbing of the carotids, dyspnœa, cough, and gastric irritation from passive congestion.

Strophanthus, in ten-drop doses in laurel-cherry water, improved his condition so that he could perform his daily labor for over a year. Recently I was called to see him and found him in a very bad condition, unable to lie down or sleep; œdema of the legs, congestion of the liver with slight jaundice, and very weak irregular heart. He had not been taking the strophanthus regularly, and thinking that perhaps it had lost its effect, I gave caffein with benzoate of sodium, 7½ grains daily, which is highly recommended by Dujardin-Beaumetz in such conditions. No effect. I then gave the more soluble citrate of caffein, increasing his distress. He was also taking citrate of potash and buchu. I then determined to again try strophanthus, and gave twelve drops three times daily with immediate improvement, œdema disappeared, could lie down and sleep, feeling much better, the diuretics were also continued, with moderate catharsis.

I have at present a young woman with the same double lesion, who is taking seven drops three times daily, with improvement. The drug has seemed to me to be especially useful in mitral stenosis, or double lesion at the mitral valve. If its want of action on the vascular system should be proven in man, it would be a great point in its favor, and would make it useful in cardiac failure in pneumonia, typhoid fever, and kindred conditions.

Convallaria maialis was used as early as the sixteenth century for diseases of the heart. According to Sée, it augments vascular pressure, and the ventricular energy, is useful in palpitations, and cardiac arythmia, even if due to valvular lesions. He also claims that its diuretic powers are greater than those of any other cardiac tonic. Others regard it as a very moderate diuretic.

Caffein is particularly recommended by Dujardin-Beaumetz in asystolic conditions; I have not had marked success with it in such conditions; its action is similar to digitalis. Huchard regards it as a true cardiac tonic and diuretic in last stages, to be given with sodium benzoate in distilled water. Semmola has found caffein of great

[1] A solution of one part of digitalin in 20,000, when passed through the vessels of the frog, contracted them so as to prevent the passage of the solution. A solution of strophanthin, one part in 3,000, caused no noticeable change, and only a slight transitory action by a solution of one part in 2,000.

[2] Rummo and Ferranini claim that spartein and caffein affect the cardiac nerves and the muscle little, or not at all; adonidin and convallaramin, both the nerves and muscle simultaneously; while digitalis, strophanthus and its alkaloid affect the muscle primarily, and the nerves secondarily.

value in cardiopathies of bulbar origin and cardiac arythmia.

Spartein is hardly reliable in serious heart failure; in functional disturbances, in neurasthenic subjects, or where compensation is not seriously interrupted, it may be useful. Its action is rapid, but it is not always well borne by the stomach. From two to five grains daily may be given.

Adonis æstivalis, and adonis vernalis belong to the category of heart tonics, and are said to be good sometimes where digitalis fails. In the various other drugs, from which good results have been obtained are generally found the same or similar alkaloids which give to the above remedies their virtue.

Attention should always be given to the state of the abdominal viscera in treating heart lesions, and particularly the kidneys. I will not enter into a discussion of the indications for diuretics, cathartics, etc., but in many cases more can be accomplished toward removing œdema and effusions, and the many results of cardiac failure, by proper management of the secretions and excretions than can be done by the use of those remedies which affect the heart alone; and the judicious combination of this branch of therapeutics, with that applying to the heart, becomes of supreme importance in the management of the later stages of cardiac affections.

Contraction of the smaller arteries with increased arterial tension, is a condition often associated with cardiac disease; heart failure being directly due to this condition, which may also be associated with chronic congestion, chronic degeneration, and chronic inflammation of the kidneys—which conditions are well described by Delafield. The arteries may be slightly or considerably thickened, due to a more or less irregular increase of the tissue of the intima; the contraction may be spasmodic and temporary, or may be continued.

This condition may be due to direct irritation of the arteries by a pathological condition of the blood, or such a condition of the blood may disturb the nervous centres controlling the vaso-motor system; the cause is not quite clear. This condition is most often associated with aortic disease, and the association of aortic changes, general arterio-sclerosis, and chronic kidney changes, would indicate that some pathological state of the blood is the source of these various changes.

Vascular dilators are the remedies for this condition, and the efficacy of opium, as lauded by Beaumetz in aortic disease, is probably due to relief of arterial contraction as much as to any other action. I have had considerable success in relieving spasmodic intermittent attacks of heart failure in advanced heart disease through the use of opium.

I cannot take up more time by considering the kidney changes involved, but they are exceedingly interesting, taken in connection with the above condition, and should be carefully studied, as the amount of urea, albumin, and casts present or absent at various times, give valuable therapeutic indications.

---

## THE PHYSIOLOGICAL ACTION OF TYPHOID FEVER POISON.[1]

By N. S. DAVIS, Jr., A.M., M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE, CHICAGO MEDICAL COLLEGE.

The only positive evidence of the existence of typhoid fever is the discovery after death of typhoid ulcers and signs of the accompanying catarrhal inflammation in the intestines. Except in rare cases, a diagnosis can be made during life without difficulty from the presence of the so-called "typhoid state" and the symptoms of the intestinal lesions.

While studying annually a rather large number of cases of this disease, the very considerable variation in intensity of some of the symptoms and variable existence of others has attracted my attention and called for explanation. For example, one of the most frequent variable symptoms is that of sweating. Often we see in the hospital patients lying side by side, suffering with equal severity in the same stage of the disease, the one bathed with a constant, profuse perspiration, and the other with a skin as constantly dry and hot; or, again, one will be in wild delirium, and the other stupid or semi-comatose.

The question then suggests itself, what symptoms are the result of the typhoid infection, and what the result of superimposed infection or of other causes? From a clinical study these questions can be answered only imperfectly.

Cases are recorded in which death has occurred from sudden intestinal perforation, the result of typhoid ulceration in persons who were not feeling ill until the fatal catastrophe occurred. It is evident, therefore, that typhoid inflammation of the intestines may exist without coincident and resulting typhoid intoxication. This necessitates distinguishing between the primary infectious agent causation of the disease, and what, for convenience, I term in this paper typhoid poison or intoxicant, which results usually from the development of the disease in the infected person. This fact of the occasional absence of typhoid intoxication in those infected can be explained in several ways: Either the intoxicant is eliminated as fast as manufactured or destroyed before gaining access to the nervous system and tissues generally, or it is not absorbed from its source. The typhoid poison is probably manufactured in the inflamed adenoid structures of the intestines, and possibly also within the intestines. In apyretic cases there is no evidence that absorption from the intestine or its walls is hindered. Elimination of poisons absorbed from the intestines takes place by the liver, or by organs in the circulatory tract more distant, such as the kidneys, lungs, and skin. Absorption of the typhoid poison we might, *à priori*, suppose would take place chiefly, if not wholly, by the lymphatics. Therefore it would be likely to be disseminated throughout the system and produce some general disturbance before it could reach the organs of elimination. It does not seem probable that the liver is the organ by which general infection is prevented, for what evidence we have points to a diminution of the eliminating power of this organ during an attack of the disease. I think we must conclude that in such cases the toxic principle is destroyed and rendered inert before absorption occurs, but in what way we do not yet know. It is also evident from these cases that the general symptoms, such as fever and tissue-waste, are not dependent directly and wholly upon the local inflammation in the intestines, but upon something that may originate from this inflammation. Considering this subject from a clinical standpoint, the physiological changes which occur with uniformity in all cases that present general symptoms must be regarded as due to the typhoid intoxicant, and such as are of variable occurrence as due to the superimposed infection or to changes in the susceptibility of organs.

All practitioners meet with mild cases and abortive ones. These are probably to be accounted for, as are the febrile cases, by supposing that the poison is partly destroyed, and that it finds its way into the general circulation in small quantities, or sometimes intermittently.

The most characteristic results of the disease are therefore the intestinal lesions, such as the diarrhœa that results from the catarrhal inflammation which accompanies the more characteristic typhoid inflammation of the adenoid bodies of the intestines; the hemorrhages which occasionally occur, and result from ulceration of the intestines; the perforation, which still more rarely occurs, and produces various forms and degrees of peritonitis.

Fever is the most characteristic of the effects common to all cases of generalized typhoid poisoning. It is undoubtedly due to the action of the toxic agent upon the

[1] Read before the American Academy of Medicine, November 14, 1889.

nervous system. It is generally said that the increase of bodily temperature is accompanied by, and grows out of, an increase of cellular metabolism, chiefly in the muscles and large glandular organs. This does not seem to me to express the whole truth. There is an increase of metabolic activity, but not of the usual or physiological type, for it does not result in the customary products of physiological metabolism, such as normal secretions from gland-cells or mechanical energy from muscles. Just what the chemical products of this fever metabolism are, and just how they differ from the products of physiological cell-activity, chemists have not yet told us. The most exact information that we have of the character of these changes is obtained from a study of the waste products of the system which are eliminated by the kidneys. In this way it has been shown that the nitrogenous elements of waste are eliminated in a comparatively imperfectly oxidized condition. Therefore, in the severest cases urea is excreted in diminished amount, and especially in diminished amount as compared to the total amount of nitrogenous matter eliminated. In milder cases, and in the majority, the amount of urea excreted is actually increased; but still, compared with the total nitrogenous matter, its proportion is small. Among these nitrogenous bodies we may surmise, with considerable assurance, that there are leucomaïnes.

These urinary changes have been most thoroughly studied and interpreted by Robin. Henocque has reached practically the same conclusion, *i.e.*, that oxidation is imperfectly accomplished, by a different method of inquiry, by the use of his hæmatoscope, which shows that the quantity of oxyhæmoglobin in the blood is diminished, and that the activity of its reduction is lessened. Flint has urged that water is normally formed in the system by oxidation, and that in fever the formation of water is diminished or suppressed. This view is based chiefly upon facts obtained from the clinical study of typhoid. If true, it, too, means that oxidation in the physiological manner is in typhoid diminished. But, as Regnard's experiments have shown, carbonic-acid gas is exhaled in increased amounts, and oxygen is taken up in still larger proportion, and is used, but more slowly than natural (Henocque), in the production of new compounds or of those peculiar to the disease. All these facts viewed side by side with the impressive clinical lesson which is taught by every case of typhoid, that an excessive waste is taking place, point unmistakably to an excessive but perverted metabolism.

The molecular changes in the cells of many of the tissues of the body which grow out of these chemical ones point with equal clearness to the pathological character of the cellular activity which has existed during the fever. These grosser changes consist chiefly in the production of cloudy swelling of the cells of many glandular organs, and subsequently, in some instances, of fatty degeneration. In muscle-fibres here and there are seen spots of waxy degeneration. Such changes as these are not peculiar to typhoid fever, but are to be found in other diseases when the metabolism of the cells is similarly affected. Not only do anatomical changes thus grow out of the chemical, but the physiological action of many organs is quite as strongly and deleteriously modified. This increased metabolism of fever is supposed, from evidence obtained from pyrexias which have been experimentally produced, to be governed by the nervous system. I know of no evidence to show that the perversions of tissue change which are peculiar to each species of fever are dominated by the same agent. That there are characteristically different metabolic products produced by scarlet fever and small-pox, by typhoid and rheumatism, which produce different forms of intoxication, is undoubtedly true. These peculiarities may be due to the direct action of the poison on the tissues. I do not wish to imply that the sole intoxicant in all fevers is the result of perverted tissue-change, for poisons of extraneous origin undoubtedly often play a prominent part in the production of characteristic symptoms.

Inhibition, or, at least, very great diminution, of tissue-repair is a change quite as important and characteristic of fever as perverted metabolism. Indeed, the total retrograde tissue-change during fever is less than during health, but compared to tissue-repair under the same conditions of diet, rest, etc., it is great. I have often administered to typhoid patients quantities of liquid nourishment as great as would maintain in health an equilibrium of strength, and apparently, judging from the appearance of the stools, the food was properly digested and absorbed; still these patients steadily lost flesh and strength. Under the condition of the fever, there was evidently a greatly lessened appropriation of nourishment.

The pyrexia is undoubtedly almost entirely due to the comparatively excessive tissue-waste, for the mechanisms of heat-dissipation are in no constant state in typhoid fever. Heat-dissipation takes place chiefly from the skin and lungs, and is influenced much by the amount of moisture which is eliminated from these surfaces. But the elimination of the latter varies greatly in different cases, and on different days in the same case, without materially influencing the degree of bodily heat. Compared with the normal state, an excessive heat-radiation always exists in fever.

The blood does not undergo uniformly any morphological changes. In the larger proportion of cases it is probable that a comparative excess of white corpuscles exists. During the height of the disease, often a greater number of corpuscles per cubic centimetre can be counted than is natural. In a word, the blood is more concentrated. During convalescence, on the contrary, the blood becomes less concentrated and the proportion of corpuscular elements is reduced. The concentration of blood does not seem to be dependent on the diarrhœa which is so apt to be profuse, nor upon the hemorrhages, nor upon diaphoresis, for it can be observed even when none of these causes is especially active. This fact has suggested the thought that probably the diminished formation of water within the body, which Flint had pointed out as occurring in fever, may account for the diminished amount of water in the blood. During convalescence the volume of the blood is restored, but the red corpuscles, which undoubtedly are in part destroyed during the active progress of the fever, are not so easily restored, and therefore a true anæmia is produced. Although the corpuscles are apparently more numerous than normal during the height of the fever, their sudden and great reduction in number during convalescence can only be explained by supposing that destruction was going on, although masked by the concentration of the blood. Fibrin does not usually form as abundantly in typhoid blood as in healthy, although this is not a constant or invariable characteristic of it.

During the early and progressive stages of typhoid the peripheral vessels are relaxed and the blood-pressure in them lowered. Whether this change is effected by agents acting indirectly through the nervous system, so that the normal vascular tone is lessened, or by agents acting directly on the vascular walls, it is impossible to say. Probably both the nervous and muscular mechanisms are simultaneously influenced in the same direction. The heart muscle is frequently weakened by degenerative changes, which are the result of a morbid metabolism similar to that taking place in the other tissues of the body. The quickened pulse is shown by Martin to be due to the effect of the heated blood upon the heart itself. The degenerative changes account for the weak and quick pulse which is often noticeable long after the pyrexia has ceased.

The increased frequency of respiration is fully explained by the action of the heated blood upon the respiratory centre. The nasal passages are rarely inflamed, although they are usually dry. The pharynx, and usually the larynx, are in the same condition. The bronchi are almost uniformly more or less inflamed. So usual is this bronchitis that by many it is regarded as due to the typhoid infection. Proof of this, I think, is insufficient, and such an explanation is certainly unnecessary; for the dry

condition of the mouth and throat, and the infrequent acts of swallowing, of coughing, or of otherwise removing what gathers about the larynx, trachea, or bronchi during the period of mental dulness, readily explain many of the cases of true bronchitis. Often the physical signs of a mild bronchitis are present very early. This, I believe, is due to an unnatural dryness of the bronchi rather than to inflammation, and is similar to the change that is observable in the pharynx and mouth. The dryness is the result of diminished secretion by the mucous glands.

When moist râles are heard in typhoid bronchitis they are due to inflammatory exudates. Most of the other changes that occur in the lungs and air-passages are superimposed and complicating diseases, and not direct outgrowths of the fever.

In typhoid fever there is a diminution of normal glandular activity, as a rule. This is well illustrated in glands along the alimentary tract. The dryness of the throat and mouth is too well known to need mention. This is due almost exclusively to the diminished formation of saliva. We possess little experimental evidence of the condition of the secretions in the stomach. The deleterious influence of solid food upon the inflamed intestines is well known. Disinclination for food, and the occasional vomiting of undigested food, point clearly to slow and imperfect digestion. Glujinski, in a moderate number of cases, found by direct examination of the contents of the stomach that hydrochloric acid was wanting except during recovery, but that pepsin was secreted as usual. This change is not due to the pyrexia, evidently, for digestion is not at all uniformly interfered with in chronic pyrexias.

The diminution in the amount of urine during the period of fever, its acidity, high specific gravity, and the increase in the urea and uric acid in it, are changes too well known to need recalling. They are dependent largely, if not wholly, upon the changes that first occur in the general metabolism of the tissues. That they are thus dependent seems evident from the fact that the degree of change in their quantity depends upon the severity and progress of the pyrexia and other general symptoms. They do not depend directly upon the degree of temperature, but change with its permanent fall. On post-mortem examination the kidneys are usually found somewhat enlarged, and their epithelial elements in a state of cloudy swelling. It is probable that these changes are the result of the perverted metabolism which exists in all the tissues, and in the renal among the rest. Necessarily, these changes must interfere more or less with the functional power of the organ. Uric acid and the incompletely oxidized waste-products are increased out of proportion to the urea. Ammonia and kreatinin are voided in increased amounts. The chlorides are usually diminished, and the coloring matters increased. All of these changes are most intense in the first, and early part of the second, week. After this, the urine by degrees becomes more abundant, and the proportion of the constituent elements approaches more nearly the normal. During convalescence it is pale and dilute.

Among the symptoms most uniform in their occurrence are those connected with the nervous system. Indeed, they chiefly characterize the so-called "typhoid state." While there are a large number of cases that present varied mental symptoms, the greatest number are very uniformly characterized. Usually the disease is introduced by headache. This, I believe, is largely the result of changed blood-pressure, and possibly of a commencing change in the nutrition of the brain-tissue. Soon pain ceases, and mental hebetude, or greater or less stupidity, is noticeable. The patient gradually becomes less and less conscious of his surroundings, and when addressed, or requested to make certain motions, responds with slowness, as his mental acts are retarded. Forgetfulness is also a usual characteristic. The stupidity gradually is intensified until a semi-comatose condition is developed. The hebetude is not due to somnolence. It is accompanied by more or less of delirium, which generally shows itself in low mutterings or occasional starts or attempts to rise, that are readily pacified and quickly checked by the attendant.

In a smaller proportion of cases the delirium is persistent, and even violent. I wish particularly to call attention to the marked similarity of these symptoms in their development to those progressively produced in narcotic poisoning. There is a stage of mental sluggishness or torpidity which so far prevents the action of the higher inhibiting centres, that more or less of delirium is produced. This inhibiting may go so far as to permit wild delirium, just as we find in the narcotic poisoning of certain individuals delirium, when ordinarily we would expect stupidity or somnolence. Usually, as the poisoning deepens, more or less complete unconsciousness develops, which rarely passes into actual coma. This progressive poisoning, or narcosis, if we may call it such, is probably the result of the successive involvement of different parts of the brain, and of their varying susceptibility in individual cases to the poisons generated in the course of the fever. Variable phenomena are cutaneous hyperæsthesia, anæsthesia, noise in the head, dizziness, muscular tremors, etc. These are probably due to accidental causes, or to idiosyncrasies of the person, and not directly to the typhoid poison.

But, we ask ourselves, how are the usual mental symptons of typhoid produced? Are they the result of the direct action of the infective agent or cause of typhoid fever, or of some agents produced within the body as a result of the fever and changes incident thereto? Robin has insisted, in answer to this question, that the phenomena are the result of the accumulation in the system of products of unnatural or incomplete tissue-change, which act poisonously upon the nervous system. He would conclude, therefore, that the infecting agent was not the direct cause of the mental symptoms. To substantiate this view he points to the fact that, when the so-called typhoid state develops, there is always a marked diminution of complete tissue-oxidation. The same symptoms and the same pathologico-chemical conditions are observable in other diseases than typhoid fever, as, for instance, at times in pneumonia and rheumatism, although there is no anatomical evidence of a complicating typhoid. The experiments of Robin and deductions therefrom are all the facts that as yet throw light upon the question which we have just asked.

The dry skin of most typhoid patients is the result of the same diminished functional activity that we observe in the glands of the mouth and elsewhere. It is probable that the diminished quantity of water in the system also aids in producing the functional inactivity. A positive cause of the profuse perspiration that is occasionally seen cannot be named. It is quite probable that it is an attempt to vicariously do work which the kidneys cannot accomplish; but it may be the result of the presence in the blood of some sudorific. That the lack of perspiration is due to an active cause, and that it is not a passive effect, is evident, as the hot blood would of itself, in a normal condition of the tissues, be a powerful diaphoretic. An explanation of the characteristic rash is wanting. The rare pustular and furuncular eruptions are undoubtedly produced by superimposed infection. How the typhoid poison is eliminated is problematical. The most natural supposition is that it takes place through the kidneys.

The limits of this paper will not permit a discussion of numerous other variable changes and complications, which are in some instances the result of coincident infection by the poison of other diseases, and in others the result of the peculiarities of susceptibility of organs and tissues in given cases.

We may summarize our conclusions as to the physiological action of the typhoid poison as follows: 1. The cause of typhoid fever produces inflammation of the adenoid bodies in the intestines; and the accompanying

catarrhal inflammation. 2. General symptoms are not the result of the typhoid ulceration of the intestines, but of something (an intoxicant) formed and usually absorbed in the course of the inflammation. 3. The lymphatics are probably the vessels by which the toxic agent is at first chiefly carried from its source. 4. The typhoid poison, presumably by acting upon the nervous system, produces pyrexia, which is the result of increased tissue-change that probably, by the direct action of the poison on the tissues, is perverted in a manner peculiar to the disease and is characterized chiefly by imperfect oxidation. 5. The typhoid poison also inhibits tissue-repair, and therefore produces bodily waste. 6. These tissue-changes result in various anatomical changes, such as cloudy swelling of most glandular organs, waxy or fatty degeneration of many muscles, and destruction of some blood-cells. 7. They also result in various physiological changes, such as diminished secretion from glands, salivary, gastric, hepatic, renal, sudorific, and probably bronchial mucous. 8. The heated blood increases the rapidity of the respiration and of the heart's action. 9. Some of the products of the perverted tissue-changes act toxically to the nervous system, and produce the mental and nervous symptoms characteristic of the disease. 10. Bronchitis is probably the result of irritation of the dry and unprotected membranes by the inspired air. The frequent coincident attacks of catarrhal pneumonia are due to an extension of the bronchitis; croupous pneumonia to superimposed infection; hypostatic engorgement to weakened circulation, respiration, and the prolonged dorsal decubitus. 11. Peritonitis is due to the extension of the original inflammation from the intestines to the peritoneum, or more frequently to perforation of the intestine by ulceration. 12. Parotitis is due to superimposed infection, probably from the mouth, which takes place with especial ease while the gland is functionally inactive. 13. Pustular eruptions are also due to superimposed infection.

## Clinical Department.

### FATAL POISONING BY CHLORATE OF POTASH.

By WILLIAM ANDERSON, M.D.,

BROOKLYN, N. Y.

In view of the wide-spread domestic use of chlorate of potash, and from the fact that fatal cases of poisoning by it are somewhat rare, I consider it useful to report the following case, the first one I have met in nearly twenty years' practice.

Mrs. M——, aged about seventy, in fair health, but suffering from constipation, dissolved nearly one ounce of chlorate of potash in water, and drank it all, thinking it was Rochelle salts. No special disturbance was felt at the time, but the mistake being discovered about an hour after, some mustard and oil were taken, to produce vomiting, which was accomplished. Two hours after the drug had been swallowed I was called in, and found the old lady quite comfortable, suffering no pain or distress of any kind. Being misinformed as to the quantity of the drug used, and believing it to be probably about two drachms, I gave a favorable opinion, prescribed a dose of castor-oil, to be followed by a solution of bismuth. Four hours afterward I was again called, and found the patient in a state of collapse. While defecating, she had fainted. The lips were blue, the tongue of a purplish color, and the face ashen. On rallying a little, she declared she had no pain, but immediately commenced to vomit a profusion of mucus. There was no sign of blood in the discharge. The temperature was 100° F., and the pulse about 100—weak, but not irregular. No oppression of breathing; feet warm. Judging that trouble was to be apprehended from the heart, I prescribed small doses of digitalis and whiskey to be frequently given during the night. She kept quiet and drowsy from this time, 10 P.M., till about 3 A.M., when she went asleep (probably became comatose), and died quietly about 6 A.M., fifteen hours after partaking of the poison. She urinated freely after taking the draught, but I did not get an opportunity to examine the water. As I did not see her during the last eight hours of life, the immediate symptoms preceding death can only be guessed at; but I believe it might be said she died of "heart failure."

### A CASE OF UNUSUAL TOLERANCY OF THE PREGNANT UTERUS.

By CHARLES L. LANG, M.D.,

NEW YORK.

On the 10th of last May I happened to be in S——, a lovely summer-resort in this State. During the day Dr. S——, one of the best local physicians, requested me to see with him a case in consultation. He had begun the treatment three months previously, the patient at that time being a few months past her confinement, which had left her not as well as she wished. The doctor diagnosed subinvolution of the uterus with considerable peri-uterine cellulitis. His treatment had been fairly regular from February to May, and had consisted of local applications to the cervix and fornices, the use of the hot douche, and, as he believed, two very thorough scrapings of the endometrium with Thomas' dull curette.

Arrived at the home of the patient we found Dr. W——, whom the husband had summoned to meet us, as he was not satisfied with the progress his wife was making. After Dr. S—— had repeated the history of the case, we each made a vaginal and bimanual examination of the patient. The uterus was as large as it should be at four months' pregnancy. Then Dr. S—— introduced the curette for the purpose of measuring the depth of the organ, and it passed in easily till the ebony handle blocked up the os. The diagnosis of chronic metritis was reluctantly made, none of us being very clear about the case. Pregnancy would seem to be excluded both by the treatment and the previous history. However, Dr. W—— writes me that the case being left largely to nature, and no more active treatment of the uterus being allowed, she was delivered of a healthy baby late in September.

180 East Seventy-second Street.

### HÆMATEMESIS IN TYPHOID FEVER.

By A. A. GILLETTE, M.D.,

WESTERNVILLE, ONEIDA COUNTY, N. Y.

In The Medical Record of November 16th two cases of intestinal hemorrhage are reported in which blood was vomited, but none passed by the anus.

On August 5th I lost a typhoid-fever case in a similar manner. The patient was a young farmer, about thirty-five years of age. The fever was well marked and typical, with diarrhœa, tympanites, pulse 120, and temperature of 105° F., with slight morning remissions. He was just beginning the third week of fever, and all seemed to be going well, when I was hastily summoned, early on the morning of the above date, to find my patient in a state of collapse. During the previous night, while his bowels were moving, he was suddenly seized with agonizing abdominal pain, followed by increased tympanites and tenderness, and accompanied by a severe chill. His agony was so great that I was sent for at daylight. I found my patient with a pulse so rapid and feeble that it was difficult to count.

Soon after my arrival he began to vomit large quantities of blood. The friends said there had been none in the stools, and this was confirmed by a perfectly bloodless movement a short time before death, which soon followed.

THE MEDICAL RECORD:

## THE NON-TUBERCULAR AND NON-CARDIAC HÆMOPTYSES OF ELDERLY PERSONS.

AT a recent meeting [1] of the Medical Society of London, Sir Andrew Clark read a paper with the above title, in which he described a form of pulmonary hemorrhage occurring in persons somewhat past middle age, and which is not associated with any tuberculous or cardiac affection. His attention was first called to this condition many years ago by the occurrence of a fatal case of hæmoptysis in a man between fifty and sixty years of age, who had been admitted to the London Hospital for treatment of a subacute bronchitis. The patient had for several years been the subject of a moderate progressive osteo-arthritis, and for the past four or five winters had suffered from severe bronchitis. It was during one of the latter attacks that he was admitted to the hospital. About two weeks after admission he began to cough up small quantities of blood at short intervals. In spite of rest, restricted diet, the application of ice to the chest, and the liberal use of astringents, the bleeding persisted, and within a week the patient died. At the autopsy the heart was found to be normal, and no evidence of tuberculous disease could be detected anywhere. Within the lungs were seen several isolated patches of emphysema surrounded by hemorrhagic extravasations. Examination under the microscope showed that the seat of the hemorrhage was in the immediate neighborhood of these emphysematous patches, and that the minute arteries in these localities were always diseased, the structural changes being limited to nuclear proliferation in the middle coat, and an amorphous and hyaline infiltration of it and of the intima. The first change, the author believed, occurred in a terminal branch of the pulmonary or bronchial artery, and this resulted in obstruction of the blood-supply throughout a certain territory. Following this was degeneration of the capillaries and venous radicles, determining a true atrophic emphysema, and, the integrity of the vessels being thus impaired, the formation of thrombi or recurrent conditions of pressure brought about the fatal hemorrhage.

Subsequent to this observation, Sir Andrew met with quite a number of similar cases, in all of which the usual treatment by astringents was without effect. Finally he determined to try another method of treatment. In a case which he saw in consultation, after having instituted the ordinary treatment without obtaining an arrest of the hemorrhage, he put the patient upon a light and rather dry diet, gave a dose of calomel at night followed by a saline cathartic in the morning, and ordered an alkaline mixture containing ammonia. This was entirely successful, the bleeding ceased within thirty-six hours, and the patient recovered perfectly.

The following are the author's conclusions in regard to this form of pulmonary hemorrhage:

1. There occurs in elderly persons free from ordinary diseases of the heart and lungs a form of hæmoptysis arising out of minute structural alterations in the terminal blood-vessels of the lung.

2. These vascular alterations occur in persons of the arthritic diathesis, resemble the vascular alterations found in osteo-arthritic articulations, and are of themselves of an arthritic nature.

3. Although sometimes leading to a fatal issue, this variety of hæmoptysis usually subsides without the supervention of any coarse anatomical lesion of the heart or of the lungs.

4. When present, this variety of hemorrhage is aggravated or maintained by the frequent administration of large doses of strong astringents, by the application of ice-bags to the chest, and by an unrestricted indulgence in liquids to allay the thirst which the astringents create.

5. The treatment which appears at present to be the most successful in this variety of hæmoptysis consists in diet and quiet, in the restricted use of liquids, and the stilling of cough; in calomel and salines; in the use of alkalies with iodide of potassium; and in frequently renewed counter-irritation.

## COMPULSORY VACCINATION IN THE UNITED STATES.

WITH the exception of Massachusetts, there is, so far as we are informed, no State in this country in which vaccination is directly and specifically required of all children. Practically, however, in most States vaccination is indirectly made compulsory. Dr. Rauch, Secretary of the Illinois State Board of Health, recently made some interesting statements regarding this subject before the Royal Commission on Vaccination (*The Lancet*). Dr. Rauch said that in the army, orders as regards the vaccination of men in regiments were carried into effect on a mere rumor that small-pox existed in some neighboring brigades. Again, during the Chicago fire, when four thousand people were housed in a barrack, the importation of one case of small-pox led to an order that every person should be vaccinated, and all obeyed except "an Englishman," who threatened anyone who should vaccinate his children. Nevertheless they were subjected to the operation, and it may be recorded that, a few weeks afterward, the man, finding his children were saved from small-pox, made an apology for his behavior. In November, 1881, small-pox was on the increase in Chicago and Illinois, and an order was issued for the vaccination of all pupils admitted to public schools in each of the twelve thousand school districts of the State, and in the end six hundred and fifty thousand children were vaccinated in the public and parochial schools. Vaccination is permissive, but school attendance is compulsory, and all attending school are compelled to be vaccinated. And if

small-pox is found in a house the building is "quarantined, placarded up, and everybody vaccinated and revaccinated." Here, in the case of others than school-children, the compulsion is indirect. Those submitting to vaccination are allowed out of their houses, and have certain privileges; those refusing are compelled to remain in-doors under a police requirement. Much the same style of compulsion applies to persons entering the State of Illinois, the unvaccinated being subjected to the operation either before starting for their journey from the port, or in the railway cars during transit. If they refuse —and a case of three Englishmen was cited as to this— they are not allowed to enter the State. In the end, they preferred Illinois and vaccination to being sent back to the place whence they came. Apart, therefore, from compulsion as to school-children, the compulsion as to vaccination in Illinois is actually on a very wide scale, and it mainly comes into operation at times when small-pox is imminent or actually prevalent.

In England the law compels all children to be vaccinated. This arouses a good deal of opposition, and not without reason. It appears to us that the matter is managed much more judiciously and sensibly in this country.

The State has no right to vaccinate a child as long as the child is kept at home and is not a source of public danger. But if the child is to enjoy the benefits of education and the privilege of coming in contact with others, then the State may take precautions and enforce vaccination.

## FLORIDA JOINS THE PROCESSION.

THE question of the State regulation of medical practice is one concerning which some honest difference of opinion exists even within the ranks of the profession itself. An esteemed correspondent has recently offered as an objection to such measures that any attempt to control medical practice is an encroachment upon personal liberty, and he holds that public opinion will of itself, and in its own good time, bring about the elevation of the medical standard of education so that no State interference will be necessary. The same argument might apply equally to bunco-steering and sawdust swindles. There can be no question that public opinion is against such practices, yet few sensible men will deny the right of the State to repress them whenever it has the opportunity. We may admit that society frowns upon dishonesty, that the schools teach morality, and even that the world is growing better every day, but we cannot yet afford to erase all laws from the statute-book, to open the prisons, or to close the courts.

It is possible that a better way to protect the community from the injury done by charlatans and ignorant practitioners than State regulation may yet be found, but at present none other exists in practical shape. Whether that will be effectual can be demonstrated only by a practical experience, and for this reason, if for no other, we are glad to see one State after another falling into line and putting to the crucial test of actual trial the utility of such a measure.

Florida is the latest of the commonwealths to pass a law of this nature. The act provides for the appointment of a board of medical examiners in each Judicial District, and in addition one board of homœopathic medical examiners for the whole State. The members of these boards are to be practising physicians of good standing and graduates of some medical college recognized by the American Medical Association and by the American Institute of Homœopathy, respectively. They are to be appointed by the Governor of the State and are to serve for four years. The boards are to meet twice each year in their respective districts for the examination of candidates and the granting of certificates. The subjects for examination, as specified in the act, are anatomy, physiology, surgery, gynecology, therapeutics, obstetrics, and chemistry; but, strangely enough, no provision is made for materia medica or practice of medicine unless therapeutics can be construed to embrace both these branches. Only those receiving certificates shall be entitled to practise medicine in the State, but those already engaged in practice at the time of the passage of the act need not undergo an examination, the presentation of a diploma from some recognized medical college being sufficient to entitle them to a certificate from the board.

Governor Fleming has requested the State Medical Association, through its president, Dr. R. A. Lancaster, to recommend physicians for appointment on the several examining boards, and it is believed that all the boards will have organized and held their first examination before the beginning of the new year.

It will be seen that this act differs in some respects from those already in force in some of the other States, and it would seem that the framers of the law might have done better had they followed more closely in the footsteps of their predecessors in some other parts of the Union. Nevertheless this is a beginning, and we hope the time is not far distant when every State will have some such law, and we shall then learn whether the community is able or not to protect itself by legislative enactment from the dangers of quackery.

## THE NOTIFICATION OF INFECTIOUS DOCTORS.

THE London *Times* is agitating the subject of placing restraint upon the practice of physicians who are attending infectious diseases. It is urged that the doctor who is attending a case of diphtheria, scarlet fever, whooping-cough, or measles, should not treat at the same time families in which no infectious disease exists. It prints the following remarks of a general practitioner upon this subject:

"He (the doctor) comes across a case of scarlet fever, small-pox, or other infectious disorder; his other patients are needing his visits—a midwifery case may be—and so he goes on with his work until his round is finished. In the evening, surgery work again. Each day brings similar work, only the infectious disorder has become more infectious. Now, how is he to prevent spreading infection, working in the way I have stated? True, he could go home and change his clothes, and in other ways disinfect himself; but does he? Does the conscientious doctor do this? And what about his own household? I certainly think with your correspondent that 'a notification of infectious doctors' is as much wanted as a 'Notification of Infectious Diseases Act.'"

This picture, though much exaggerated, is to some extent true; but unfortunately our social organization is imperfect and we see no radical way of remedying the difficulty. The

plan of having a special physician for infectious cases is utterly impracticable, especially in small towns and the country. It is the duty of conscientious physicians to disinfect themselves and protect themselves as much as possible; and, in fact, we doubt very much if infectious diseases are often carried by physicians to the houses which they visit, oftenest they bring them to their own homes because there they come in close and frequent contact with their children.

Doctors are almost universally careful about taking midwifery patients while attending septic cases, or cases of erysipelas and scarlet fever.

The public notification that a doctor is attending a case of infectious disease would instantly put a stop to their notification of such diseases, or else it would throw ninety per cent. of medical men out of practice.

## News of the Week.

THE HEALTH OF THE PRINCE OF WALES.—The Prince of Wales is said to be in poor health and suffering from great depression of spirits and weakness. It is with great difficulty that he keeps up a show of strength in striving to meet his engagements. All this, together with the rumor that he is suffering from Bright's disease, has it ssignificance.

ANOTHER CASE OF COCAINE POISONING has been reported in Philadelphia.

DEATH OF DR. TRUMAN H. SQUIRE.—Dr. T. H. Squire, widely known as one of the leading surgeons of Western New York, died at his home in Elmira after a long and painful illness. He was born in Russia, N. Y., in 1823, and graduated at the College of Physicians and Surgeons 1848. In 1861 he enlisted as volunteer surgeon in the Union Army, and earned for himself the distinction of being one of the most efficient surgeons in the Army of the Potomac. His name has also been prominently associated with the jointed catheter, which he invented, and for which invention he received the Prix Argenteuil awarded by the Imperial Academy of Medicine of Paris. He was a frequent and valued contributor to medical literature and was an honored member of various medical societies.

THE RUSSIAN EPIDEMIC INFLUENZA.—A St. Petersburg correspondent of the *British Medical Journal* describes the epidemic in that city as follows: "It is frequently spoken of in the lay papers as influenza, but the typical symptoms of this disease are far more frequently absent than present, and the only features in common are the rapid course, the extremely rapid spread, and the frontal headache, the great running at the nose and eyes being absent in all the cases that I have seen. The two most prominent symptoms in the present epidemic are those of high temperature and great frontal headache, accompanied in many cases by pain in the eyeballs, and in all by foul tongue and breath, constipation, and general *malaise*. The onset is rapid, the temperature running up at once to 39°, 40° C., or even higher. The pulse in those cases I have seen is not raised proportionately with the temperature. In some cases there are added the symptoms of catarrh of the nose and frontal sinuses, in others there are sore throat and catarrh of the deeper air-passages, and in many there are vague rheumatic pains about the back shoulders, and limbs. The duration is short, averaging from three to five days, though sometimes prolonged to six or eight days, or even longer, and convalescence is rapid."

THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF MARYLAND proposes to adopt a three years' graded course of instruction, and requires a general average of seventy-five per cent. of those who pass the examinations. The leaven of Johns Hopkins Hospital is working through Baltimore.

MEDICAL REGISTRATION IN NORTH CAROLINA.—The State Board of Health of North Carolina has issued the following: "All physicians in the State must register with the Clerk of the Superior Court before January 1, 1890, if they intend to practise thereafter and collect their fees for services rendered. There will be no subterfuge allowed. The law must be enforced."

A FIRE BROKE OUT IN THE PRESBYTERIAN HOSPITAL of this city on December 19th, and destroyed most of the north wing. Eighty-one patients, who were in this wing, were safely transferred to other institutions, and no lives were lost. The incident showed how generously New York is supplied with hospital accommodations. One hospital offered to take thirty patients, another eighty, another sixty. The fire will not cramp the hospital accommodations of the city. The loss to the hospital is said to be fully covered by insurance.

DR. CHARLES O'DONOVAN, a prominent physician of Baltimore, and President of the Alumni of the Maryland University, died December 23d, of heart trouble.

THE LATE PROFESSOR VOLKMANN AS A POET AND LITTÉRATEUR.—Volkmann was exceedingly skilful and elegant as an operator, he was fertile in resources, and a great inventor of new procedures. His pupils idolized him, for he was not only a teacher who joined the greatest elegance with the highest clearness of diction, but he was, up till his death the students' sincere and warm-hearted friend. In spite of his high rank in society and in the hierarchy of science, he remained a *Bursch* to the last. In Halle many amusing stories are current about Volkmann's good-humor. In the midst of his overwhelming professional work, he found time to gain the laurel wreath of a poet. His *Träumereien an französischen Kaminen*—tales which he sent home to his children during his sojourn in France in 1870 and 1871—were published under the pseudonym "Richard Leander," and had a great success. His *Lieder aus dem Saalethal* added to his literary reputation, and many of his fairy tales, told in the first instance to his own little ones, found their way to the hearts of German children. In Volkmann Halle has lost its chief medical attraction, the German army one of its foremost surgeons, and the art of surgery one of its most brilliant exponents.

THE THREE BROOKLYN FAITH-CURE FANATICS who were arrested for endangering public health by refusing to allow a sick wife and child to have medicine, were convicted, and fined $200, $150, and $100, respectively.

A LARGE BRAIN.—The brain of the insane homicide and suicide Daley was found to weigh fifty-nine and one-quarter ounces, and to show no gross pathological lesions. This is just the weight of the murderer Ruloff's brain; an ounce heavier than Jim Fisk's, and six ounces heavier than Daniel Webster's.

# Correspondence.

## CIVIL SERVICE EXAMINATIONS FOR MEDICAL MEN.

To the Editor of The Medical Record.

Sir: During the weeks which have followed the publication of my letter concerning Civil Service matters in The Record of December 7th, I have received many communications from physicians, both in New York and places far away. The writers have gratified me exceedingly by upholding heartily the position I there took regarding certain municipal medical abuses; and in several instances they referred to other and additional Civil Service obliquities which they had experienced. I wish these gentlemen would publish in this journal the same statements which they have made in private. Such public evidence of approval would doubtless help in abating the abuses of which we are all aware.

To those gentlemen whose kindly messages I have received, but through stress of work have not answered, I take this means of tendering my thanks and my appreciation.

In the latest number of The Record there appear letters from Dr. Frederick Peterson and Mr. G. K. Ackerman. Regarding the first, it interested me, as I had not before heard of the examination in 1884, which this gentleman so creditably passed. However, my paper referred to New York *City* (not State) examinations, and so far as these are concerned my statements were, I think, correct.

Perhaps the profession would have been more interested, and some good might have resulted, if instead of devoting an entire article of more than a column to the details of his examination, and to laudation thereof, the doctor had said just a few words regarding present examinations—inefficient because hasty and not practical—and their accompanying political queernesses.

Regarding Mr. Ackerman: This gentleman, in his communication mentioned, cuts out a portion of my published letter and pronounces it a falsehood. This he does with such emphasis and brevity as to be equivalent to saying "damn!"—and that is all.

The portion to which he refers was, as I stated, simply a quotation on my part, which I have reason for thinking true. How it will surprise and even sadden the doctor who told me how he attained the "Summer Corps," when he learns that Mr. Ackerman contradicts him!

In the *Evening Post* of December 17th is an interview with Mr. Ackerman, in which this gentleman practically admits the more important of the facts alleged, barring the taking of the papers home by the doctor. That is, he admits that a certain few physicians were allowed a special examination a day or two later than the regular one.

If a certain one or two are, as a favor, allowed to take their examination a day or two days later than that of the vulgar herd, and are—as we are informed—asked the same questions as the latter, what fairness is there in this arrangement? Even if different questions are asked, what fairness? It is, for obvious reasons, a simple travesty on a competitive examination, and the political cloven hoof is apparent.

If the men who were allowed a later examination in this instance were *not* asked the same questions as the others, it ought to be easy for Mr. Ackerman to prove this by allowing to reporters free access to the examination-papers written both by these favored doctors, whose names were given in the *Evening Post*, and by the rest of the class.

I have no personal quarrel with Mr. Ackerman. He is probably a politician of much probity; and therefore there are a few points on which, in common with many other physicians, I find myself puzzled.

Will not some other among the professional readers of The Record add his personal quota to the problem under discussion, as, at the request of the editor, I have done?

Robert H. M. Dawbarn, M.D.

## A PROTEST AGAINST THE REMOVAL OF THE UTERINE APPENDAGES.

### A Letter from Dr. Thomas Addis Emmet.

To the Editor of The Medical Record.

Sir: In the issue of The Medical Record for December 21, 1889, my views are not clearly stated in the report on the discussion which followed the reading of Dr. Malcolm McLean's excellent and well-timed paper. Much that I did say is reported accurately, but either I failed to make myself understood, or enough has been omitted to give the impression that I was opposed to the operation for the removal of the uterine appendages.

From the beginning I have been uncompromising in my opposition to the removal of the ovaries for dysmenorrhœa and other nervous disorders, due to perverted or impaired nutrition, and where the fault lies in the nerve-centres. The training of a lifetime to close observation would save me from the error of denouncing any operation until I had clearly defined the grounds for doing so. Mr. Tate introduced a valuable procedure which has its place, but it lies in a more narrow limit than he, or many other operators at the present time, are willing to admit. It is an operation which I never hesitate to recommend, or to perform, when I think it indicated. I have simply opposed at every turn the fearful abuse of the operation which has existed, as a disgrace to the profession and as a reflection on our knowledge of the healing art. No one can deny the fact that there are members of the profession, in this city, who average more than one operation a week for the removal of the uterine appendages. My field of observation is certainly as large as any other operator, and yet I have seen but three cases during the past year when I thought the operation justifiable. I operated on these with the result of restoring two invalids to perfect health, and, I believe, no other procedure could have accomplished so much, while the third case has been but little benefited.

I have had under treatment in my private hospital a number of women where judgment had been passed, by some of our best men in the profession, to the effect that restoration to health was impossible in their condition, unless the uterine appendages were removed. I am within the bounds of truth when I state that more than half of these women have in time gotten well, and several have borne children since their discharge.

To my regret some yielded to outside pressure, and left me to have the operation performed before the necessity, at least from my stand-point, had been determined, and the others have passed away from my observation. Doubtless the greater portion of these women who were restored to health will remain sterile, from obliteration of the tubal canals, but not a single instance of insanity or of melancholia has occurred. Can the same be claimed as the result after the appendages have been removed?

Those who operate so frequently must take the trouble to keep a record of their cases, and report honestly the condition of each individual a year after the operation. Every one in gynecological practice knows that not infrequently he is consulted for relief after this operation has been performed, and where the patient has received no benefit. With not a few the suffering has been greatly aggravated by the formation, it is supposed, of peritoneal adhesions, which have been formed after the operation, and these cases are of far too frequent occurrence to be accidental or exceptions to the rule.

The burden of proof must rest with those who claim so much for the operation, to show that the after-condition of their patients justifies its frequent performance.

If they neglect to vindicate themselves the verdict must be, if it rests on the judgment of others, that while it may prove a source of pecuniary profit to the operator, a very large number of women who have trusted to their honesty have not been benefited, and their condition has been made a more deplorable one. Yours truly,

THOMAS ADDIS EMMET, M.D.

## ANTISEPTICS AND THE COUNTRY DOCTOR.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It seems as if the whole medical world was going crazy, or is already crazy, on the subject of antiseptics. The poor, miserable bacilli and cocci are hunted down, and starved, and bombarded with all sorts of antiseptics imaginable, from poisonous sublimate solutions to that vilest of all compounds, iodoform. Whether micro-organisms are the result or the cause of disease, it is now the proper thing to deluge the living tissues with all sorts of vile and poisonous substances in the name of antisepsis. I know it requires a great deal of nerve at this age of the world to even doubt aloud, much more, indeed, to put your doubts on paper. I have been a constant reader of THE MEDICAL RECORD for over thirteen years, and must confess that much that appears in it in the way of reports, communications, etc., is well calculated to amuse the country practitioner, if not to instruct him. Labor, originally a purely physiological process, is treated by the great guns of the profession in the cities as though it were pathological. The woman is harassed and tortured with antiseptic injections and antiseptic pads, etc., until she is sorry that she had a baby at all. Our city brethren tell us that nothing should be introduced into the vagina except under antiseptic precautions, as it is dangerous. In miscarriages, abortions, etc., we are told to curette the uterus and inject antiseptic solutions into it to get out all débris, etc. They omit to tell us of the great danger that not infrequently accompanies such a procedure, even death not being unheard of. In ordinary vaginal examinations, again, vaginal injections and the finger made strictly antiseptic is the proper form in the cities. I suppose, next, the act of coition will be proclaimed pathological, and not allowed except under strict antiseptic precautions. May be, in the future, eating and defecation will be subject to the same conditions. In surgery, likewise, the same craze prevails. The most trivial operations are made occult and mysterious and burdened down by elaborate antisepsis. Who shall ever know the number of victims that have been slain in the large cities, in hospital and private practice, on the altar of this Moloch of antisepsis? "Cleanliness is next to godliness," is a good text to go by in obstetrics and surgery. No surgeon should think for an instant of using dirty knives and leaving his hands unwashed in an operation. No obstetrician should think for a moment of attending a woman with dirty or pus-stained hands. Ordinary common-sense would forbid any such thing. In a moderate obstetric practice extending over a period of fourteen years, I never lost but one case, and that from cardiac embolism. I never had but one case of puerperal septicæmia, and then the woman was attended by a midwife. I have delivered by forceps and turning, after women have lain three and four days in labor, attended by ignorant midwives, and under the most unfavorable surroundings, and they all made good recoveries without a set-back. Abortion much the same way. I always used strict cleanliness, and rarely anything more than hot carbolized vaginal injections, and then not often. But I suppose some would say that this is antisepsis; but if it is, it is not antisepsis as it is understood in New York and other large cities. Last year I read the directions for conducting a strictly antiseptic labor by Professor Blank, of New York, and will only say that should the average country practitioner attempt to follow them, he would speedily lose most of his obstetric practice. About the only notice the country doctor gets, in nine cases out of ten, is when labor is in the second stage, or after the child is born, too late for elaborate antisepsis. My experience is the experience of every country practitioner, and there are no statistics to show that the common-sense, intelligent doctor in the country has any poorer results than his antiseptic-saturated brother of the city. In surgery I have never had any cause to feel dissatisfied with my results. I have performed many of the different amputations, extirpation of the breast, operation for strangulated hernia, operations on the rectum, and many more operations such as fall to the lot of the general practitioner, and sometimes I have used corrosive sublimate, carbolic acid, and other antiseptics, and sometimes hot water, and I am compelled to say that I could see no difference, as they all made good recoveries; and I do not recollect now of a case where the temperature went at any time over 99° F. Of course, strict cleanliness was observed in all of these operations. I assisted once at two ovariotomies; one case recovered and the other died on the fifth day after the operation, very suddenly, probably from heart failure. No antiseptics were used in either of these cases, only hot water and thorough sponging out of the peritoneal cavity before closing the incision, and in neither case did the temperature go at any time over 101°, and then for a short time only. I performed once the principal part of the operation of laparotomy for the relief of intestinal strangulation of a week's duration. The surroundings were of the most unfavorable character and no antiseptics were used, but the patient recovered without any unpleasant symptoms, and although the thermometer was ranging from twenty to thirty degrees below zero at the time, the patient was walking out-doors in twenty days after the operation. Strict cleanliness and hot water were of course used, and the peritoneal cavity thoroughly cleansed before closing the wound. Perhaps some of the ultra-antiseptic enthusiasts will claim it was a special dispensation of Providence that the man recovered, others that it was the purity of the climate, etc.; but I am sure there are many country doctors who have exactly the same experiences and think it nothing unusual.

One case more I wish to relate, and that will be sufficient.

Some years ago I was called in the country to see a man, aged fifty-four, who had hurt his knee. On arriving at his house I found the patellar ligament torn across and an external wound almost eight inches in length across the knee, exposing the articular surfaces of the joint. The head of the tibia had been partially broken off and comminuted, loosening a part of the articular cartilage, and the joint was full of dirt and small gravel. The family lived like hogs, and there was not a clean thing in the house. Not knowing the nature of the injuries, I had brought no bandages with me, and it being ten miles from town, I had to make them there. I got a sheet that was so dirty that I had to take it to the spring and wash it myself before I made the bandages out of it. I then cleaned out the joint, removed six pieces of bone, cut off with a scissors all the loose and torn fragments of cartilage, and closed the wound with about fifteen sutures. I used in this case only a weak solution of carbolic acid, and placed the leg on an inclined plane and used a long bandage wet with carbolized water. The man recovered without an unusual symptom and no deformity, and at the end of seven weeks could walk around with the aid of a light cane, without any trouble whatever. Motion was perfect, and the only difference he noticed was that he could not walk upstairs as easily as he could before. Every country doctor who reads this article will, I have no doubt, call to mind similar cases falling within his observation. Had this case been treated in a city with full and complicated antiseptic measures, it would be considered a great triumph of antiseptic surgery.

Gynecological surgeons tell us that antiseptics are useless in the peritoneal cavity, nay, absolutely harmful, and their use has been discontinued. Now if this is so, and I do not doubt for one instant that it is, what is the use

of such an elaborate antisepsis in ordinary operations? I must confess that I do not see any, I know that my experience is not different from others in rural practice in this regard. There is altogether too much slavishness shown to the city brother by the country doctor. It is deemed heretical to differ from the great authorities, and very few ever put their views and experience into print when they differ from the recognized leaders of the profession. Surgery has indeed made wonderful strides in the last few years, and he who stands well as a skilful and successful surgeon has much to be proud of; but I think that success and skill come more from increased knowledge and improved technique and instruments, together with surgical cleanliness, than from poisonous and vile-smelling antiseptics. The greatest surgeons differ as to which is the best antiseptic, some claiming one thing and some another, according to whim or fancy, but they all unite in claiming good results, which in the present state of human nature is not to be wondered at. Just now creolin is the coming antiseptic. In a short time it will be laid aside and some other article will take its place, only soon to be forgotten. Carbolic acid, iodoform, corrosive sublimate, and creolin, have each posed on the surgical stage, and had their admirers and detractors. A few short months, perhaps, will hail the birth of some new antiseptic that will fill a long-felt want, only to be discarded in turn by a new rival for surgical favor. In the midst of this clash of opinions and war of antiseptics, the level-headed, intelligent country doctor will keep on the even tenor of his way, and in the end show as good results as any of them. I have already written too long an article, but if any of my colleagues in the country will feel emboldened by this communication to also express their sentiments through THE MEDICAL RECORD, my highest wishes will be fulfilled.

F. W. VAN DYKE, M.D.

GRANT'S PASS, ORE.

## MALE AND FEMALE RISKS IN LIFE INSURANCE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Allow me briefly to call the attention of those of your readers interested in life insurance, to the very able report of Dr. L. D. Witherill, Supreme Medical Examiner of the "Knights and Ladies of Honor," a well-known fraternal order, dispensing life insurance on the assessment plan.

The information given in this little pamphlet is as interesting as it is manifold; but of chief importance is the result that: "Female risks have proven to be better than male risks."

We quote from pages 7 and 8 of the report:

. . . . . "Our experience during the past eleven years has been that with a larger female membership than males, the former risks have each year shown a smaller percentage of deaths than the latter."

From December 26, 1877, to February 20, 1889, *three thousand* members died. The membership during that period rose from about three thousand in 1878, to about forty-seven thousand in 1888. The number of female was always somewhat larger than that of the male members. Thus, out of a total membership of 22,046 in 1882, 10,448 were male and 11,598 were female members; while in 1888, out of a total membership of 46,935, 22,601 were male and 24,334 were female members.

In spite of this slight preponderance of the so-called weaker sex in numbers, the proportion of deaths was smaller with the latter than with the stronger sex—not only as to the ratio, but as to the actual number, of deaths. Of the 3,000 members who died, 1,601 belonged to the male and 1,399 only to the female sex. The ratio of deaths to membership for the ten years was 11.42 for males and 9.10 only for females, 10.25 being the figure for both together.

Perfectly in conformity with the results just superficially sketched is Dr. Witherill's observation—which he reaffirms with well-deserved emphasis—to wit:

"Evidently the dangers, exposures, and various vicissitudes to which males are subjected, together with the evils of intemperance, more than counterbalance the risks of maternity and the climacteric epoch."

In regard to the latter subject, is is of interest to note that of the 1,399 female deaths, 214 are attributed to "diseases of females." Of these again, 109 are directly due to childbirth (88 died in the puerperal state, 13 during childbirth—7 of these were cases of placenta prævia—the rest from various causes); 85 are cases of cancer of the female sexual organs (womb, 57, ovarian, 8, breast, 20), while the remainder is credited to a variety of diseases of the uterus, its appendages, and the pelvic tissues in general.

Scanning the numerous tables which Dr. Witherill has embodied in his report, the causes of death which in some way counterbalance this large debit on the female side are found to be principally those resulting from diseases of the respiratory organs (pneumonia more especially), of the nervous system, and accidents and suicides.

The number of all deaths by accident was 137; of these 120 were males and 17 females. The number of all suicides was 91; of these 83 were males and 8 were females.

This short synopsis may suffice to call attention to a subject which, I believe, has rarely been treated more ably and explained more clearly on the basis of absolute facts as has been done by Dr. Witherill in his report.

Yours respectfully,

GEORGE W. RACHEL. M.D.

## Army and Navy News.

*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 15 to December 21, 1889.*

ALEXANDER, CHARLES T., Lieutenant-Colonel and Surgeon. By direction of the Secretary of War, will be relieved from duty as medical director, Department of the Columbia, on receipt of this order at the headquarters of that department, and will report in person to the commanding general, Division of the Atlantic, for the purpose of preparing for, and becoming familiar with, the duties of attending surgeon in New York City. He will also, upon his arrival in New York, assume the duties of examiner of recruits in that city.

WATERS, WILLIAM E., Major and Surgeon. Will take temporary charge of the office of medical director, Department of the Columbia, upon the relief of Lieutenant-Colonel Alexander. S. O. 291, A. G. O., Washington, December 14, 1889.

BALL, R. R., First Lieutenant and Assistant Surgeon. Is relieved from temporary duty at Fort Sill, I. T., and will return to his proper station, Fort Riley, Kan. Headquarters Department of the Missouri, Fort Leavenworth, Kan., December 12, 1889. S. O. 182.

MACAULEY, C. N. B., Captain and Assistant Surgeon. With the approval of the Secretary of War, the leave of absence granted in S. O. 166, November 8th, Department of Missouri, is extended one month. Par. 10, S. O. 294, A. G. O., December 18, 1889.

MCCREERY, GEORGE, Captain and Assistant Surgeon (Fort Warren, Mass.). Leave of absence for one month is granted, to take effect upon the arrival at that post, for temporary duty, of Captain Samuel Q. Robinson, Assistant Surgeon. Par. 6, S. O. 289, Division of the Atlantic, December 18, 1889.

ROBINSON, SAMUEL Q., Captain and Assistant Surgeon (Fort Hamilton, N. Y. Harbor). Will proceed without

delay to Fort Warren, Mass., and report to the post commander for temporary duty. Par. 5, S. O. 289, Division of the Atlantic, December 18, 1889.

*Official List of Changes in the Medical Corps of the United States Navy for the week ending December 21, 1889.*

KITE, I. W., Assistant Surgeon. Promoted to be a Passed Assistant Surgeon.

STONE, E. P., Assistant Surgeon. Promoted to be a Passed Assistant Surgeon.

NORTON, O. D., Assistant Surgeon. Promoted to be a Passed Assistant Surgeon.

HENRY, CHARLES P., Assistant Surgeon. Placed on the retired list.

PICKERELL, GEORGE McC., Assistant Surgeon. Ordered to Navy Yard, Washington, D. C., for temporary duty.

## Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 21, 1889:

| | Cases. | Deaths. |
|---|---|---|
| Typhus fever | 0 | 0 |
| Typhoid fever | 16 | 5 |
| Scarlet fever | 54 | 10 |
| Cerebro-spinal meningitis | 1 | 0 |
| Measles | 55 | 5 |
| Diphtheria | 100 | 24 |
| Small-pox | 0 | 0 |
| Variola | 6 | 0 |
| Pertussis | 0 | 0 |

A REMARKABLE CASE OF MATERNAL IMPRESSION.—In a recent issue of *The Lancet*, Dr. A. R. Paterson describes a case of maternal impression as follows: "I was asked to see a woman in a neighboring village who was being attended by a midwife; the latter, however, being unable to effect delivery by herself, wanted a doctor. On introducing my finger to ascertain the presentation I perceived something unusual—a long, round, and slightly tapering fleshy substance, which struck me at the time as feeling like the shape of an ordinary carrot, but of course not so hard. But to what part of the body this substance was attached was a puzzle, until I discovered what I took to be an ear and the eyes. I then concluded it must be attached to the head. Giving a dose of ergot, and stimulating the uterus by other methods as much as possible, I soon had come into the world what I at once saw was a monster. Instantly wrapping it into the piece of flannel ready to receive it, and without saying a word either to mother or nurse, I carried it into an adjoining bedroom, followed by the latter. Here I found the fleshy substance spoken of to be projecting from the floor of the skull, the roof of which was entirely absent, and so closely did this substance resemble a cow's teat—or, as the nurse called it, 'pap'—that at the same instant we both made the same exclamation, 'How like a cow's teat!' Cautioning the midwife to observe the strictest silence while I questioned the mother, we again proceeded to her room, when I quietly said to her, 'I am sorry to have to tell you, Mrs. C——, that the child is dead, although it breathed a few moments; and perhaps it is as well, because the baby was not "all right."' 'Ah!' said she, 'I thought that such would be the case. What is wrong with it?' I replied, 'Tell me your story first. What caused you to think it would not be "all right?"' 'Well,' she proceeded, 'I got a most awful scare when I was carrying it at the fore part of my time.' Here she paused, but, leading her on by an inquiring Yes?' she went on again, 'One day I was in the cow-house, milking the cow, sitting upon the stool beside her and milking away, when a rat or something in the roof made such a row all at once as to startle the poor animal almost out of her wits, and before I knew where I was she had tumbled me on the floor, milk and all together, and there I was, lying upon my back, still hanging on to the cow's pap like grim death, and thinking that I would be trampled to death every moment. Oh, the scare! I shall never, never forget it! for it made me downright ill and nervous for weeks after it. I could not get it out of my head, and kept dreaming about it even, and I feared all along for my child.' Having thus spoken, she made signs for me to bend down my ear toward her, when she whispered: 'Has it horns upon it, doctor?' Nothing would induce the mother or friends to give up the body of the child, nor would she allow me to touch it further, which caused me the sharpest disappointment. The 'teat' seemed to be a prolongation of the spinal cord, and to be all there was to represent the brain. Otherwise the body was well-developed and perfect."

THE DIFFICULTIES OF THE MEDICAL PROFESSION.—"An Old Doctor" deplores the visible decadence of the profession in a long letter of lamentation in *The Lancet*. Among other things, he says: "In these advertising days, in medicine, as in everything else, people who know little or nothing of a subject, who presume ignorantly to address the public in the daily and weekly press, attract more notice than those who have devoted their lives to their particular work. It is a misfortune that in this country (*i.e.*, England) a very large amount of medical practice (and that the most easy and profitable) is lost to the profession by the fact that almost all chemists prescribe largely. This is a great and crying evil. The practice is, instead of diminishing, largely increasing. This should be stopped. The chemist nearly always prescribes, but generally says, to cover himself, 'If worse, take patient to a medical man.' And so the medical man reaps all the hard work (often without being paid) and the chemist most of the profits. Then, again, hospitals, both special and general, take away largely from the proper, legal, and rightful profits of the profession. The public have a notion that they get advice and medicine of the highest character from the hospitals for nothing, but if they pay for it to the general practitioner they get a second-rate article. This is a bad system. Why not set up legal dispensaries for free legal advice, free places to get married in, free clothing establishments, free meat-stores, etc., all paid for by subscriptions or rates? The fact is, the medical profession is gradually and surely committing suicide, and its career on the downward path should be promptly arrested. If we were true to ourselves (which we are not and never have been) the present increase in the profession would be insufficient to supply the needs of the public. But, if we go on working on the 'sweating system' (for who sweats more, mentally and physically, than the hard-worked medical practitioner, night and day doing his best to preserve the health and life of the people?), often indeed without reward, then we shall be fools indeed. This idea, that medical services can be had for nothing, and so ought to be paid for at that price, is spreading. We are doing away with all professional reserve. We make everything plain, and it is valued accordingly. The more a profession is lowered in the eyes of the public the less respect it receives."

THE BACILLUS OF WARTS.—Dr. Kuhnemann has found in sections of warts (*verruca vulgaris*) a bacillus which is always present in the prickle layer. It has distinctive qualities as regards its capacity for color, and is found both between and in the cells. Its form is that of exceedingly delicate, slender rods, the thickness bearing the proportion to the length of one to six. It is seldom found in the skin surrounding the warts, and is found most plentifully when the wart is recent.

Bull, Dr. Charles Stedman, contributions to the subject of tumors of the orbit and neighboring cavities, 206.
Bullein, William, notice of book by, 215.
Burnett, Dr. Charles Henry, notice of book by, 436.
Butler, Dr. C., triplets with but one placenta, 644.
Butler, Dr. F. W. P., gangrene following continued fever, 342.
Butlin, Dr. Henry T., notice of book by, 186.

C

Cabell, Dr. James L., death of, 244; memorial to, 608.
Cabell, Dr. Robert Gamble, death of, 577.
Cæcum, suppuration in the neighborhood of, advantage of early operation in, 80.
Cæsarean operation, choice of sutures for, 319; improved, *versus* craniotomy, 610.
Calculi, vesical, dilatation of the male urethra for the removal of, 101.
Calomel in croupous pneumonia, 383; in pulmonary phthisis, 95.
Cammann, Dr. D. M., some cases treated with hydrogen peroxide, 481.
Campbell, Dr. C. M., notice of book by, 188.
Canadian Medical Association, 360.
Cancer, alleged micro-organism of, 104; and age in animals, 308; colloid, of the gluteal region, 305; etiology of, 394; inoculating, 488; morphine-vaseline as a local application in, 550; of the breast, recurrence of, after amputation, 602; of the pancreas, 162; of the rectum, treatment of, 296; of the stomach, œdema as a diagnostic sign in, 484; of the uterus, treatment of, 300; primary, of the common bile-duct, 160; scirrhous, of the bladder, with vesico-rectal fissure, 152.
Canfield, Dr. William Buckingham, the relation of dusty occupations to pulmonary phthisis, 61.
Cannon-firing on the Eiffel Tower, effect of, 445.
Carbee, Dr. Moses D., death of, 487.
Carbolic acid, dangers of, 364; poisoning, soap as an antidote to, 577; synthetic, 627.
Cardiac therapeutics, 701.
Caries, green soap in, 644.
Carotid arteries, external, deligation of both, 172.
Carotid artery, an anomalous right external, 683.
Carpenter, Dr. A. B., surgical operations for the repair of ruptured perinæums, 540.
Carreau, Dr. Joseph S., treatment of diabetes, 39.
Cartwright lectures for 1889, 589, 617, 645; prize essay, 104.
Castor-oil as a menstruum for cocaine, 125; trust, 45.
Casuistry in obstetrics, 48.
Cataract, extraction of, without iridectomy, 390.
Catarrh, acute nasal, abortion of, 472; chronic nasal, treatment of, 582.
Catarrhal neuralgia, 629.
Catgut, preparation of, 40.
Cellulitis, pelvic, in women, 385.
Census, the U. S., in its relation to sanitation, 467.
Centenarian surgeon, 356.
Cervix uteri, laceration of, use of the tampon in, 285.
Chambers, Dr. Thomas King, death of, 268.
Chapman, Dr. J. Milne, on a visit to Birmingham and to Mr. Lawson Tait, 148.
Charity Hospital alumni, 686.
Charcot, Dr. J. M., notice of book by, 187.
Cheesman, Dr. T. M., apparatus for sterilizing milk, 39.
Chemical structure and physiological action, relation between, 80.
Chemical structure and physiological therapeutics, 126.
Chetwood, Dr. Charles H., the toxic effect of cocaine hydrochlorate, with report of a case, 144.
Chicha poisoning, 420.
Childbearing period, 101.
Children, "belly disorder" of, 519; dyspeptic, fat in the fæces of, 427; eczema in, 152; gastro-intestinal diseases in, climatic treatment of, 639; rheumatism in, 53; use of acetanelide for, 21; use of strophanthus for, 603.
China, dispensaries in, 102.
Chinese doctors, 447.
Chloral, and antipyrine, incompatibility of, 588; hydrate in chapped nipple, 153.
Chloralamide, 468, 503, 553.
Chlorine, germicidal value of, 115.
Chloroform anæsthesia, effects of prolonged, 461; Hyderabad commission on the action of, 434; internal use of, 72, 176; local application of, in epididymitis, 343; water in false croup, 631.
Chlorosis, simple anæmia, and pernicious anæmia, relation between, 352.
Choked disk, due to intracranial tumor, 133.
Cholecystenterostomy, 299.
Cholecystotomy, 281, 585.
Cholera, behavior of the germs of, in milk, butter, whey, and cheese, 483.
Chorea and epilepsy, treatment of, by the correction of ocular defects, 684, 688; pathological anatomy of, 437.
Choroiditis, double purulent, following meningitis, 133.
Chromic acid in sweating of the feet, 100.
Chrysarobin in hæmorrhoids, 521.
Chyle and chyle-like fluids, effusion of, into serous cavities, 351.
Chylo-thorax, 351.
Cigarettes, a report on, 291.
Cirrhosis of the liver, curability of, 211.
Civil service reform, medical examinations and, 640, 698, 712.
Claiborne, Dr. J. Herbert, Jr., a speculum for applying caustics to the deep structures of the nasal cavities, 250.
Clavicle, partial dislocation of, 202.
Climate of South Alberta, 361.
Climatic treatment of gastro-intestinal diseases in children, 639.
Climatoterapia española en la tísis pulmonar, book notice, 187.
Clothing in its relation to hygiene, 466.
Club-foot apparatus, a new, 668.
Cocaine, castor-oil as a menstruum for, 125; hallucinations caused by, 515; in surgery, 381, 566; toxic effect of, 144.
Cockcroft, Dr. William, death of, 577.
Cocoanut as a tæniacide, 400.
Cod-liver oil, administration of, 397.
Code of ethics, German, 128.
Coe, Dr. Henry C., a successful case of laparotomy and supravaginal amputation of the uterus for rupture, 478.

Eucalyptol in headache, 104.
Exalgine, 283, 399.
Execution by electricity, 103, 129, 193, 223, 377.
Experimental surgery, book notice, 218.
Expert testimony in the Cronin case, 520; the value of, 401.

Extra-uterine pregnancy dating back thirty-three years, 307; diagnosis of, 435; early diagnosis of, 309.
Eye, enucleation of, in panophthalmitis, 132; irrigation of the anterior chamber, 131; muscles of the, epilepsy and chorea in relation to the, 684, 688; rheumatism of the muscles of, 341; artificial atrophy of, as a substitute for extirpation, 503.
Eyeball, associated movements of the, 196; enucleation of, 250.
Eye-bandage, an obstetrical, 317.
Eyesight of American school-children, 17.

F

Father, the, and the race, 126.
Fat in the fæces of dyspeptic children, 427.
Faith-cure, Sam Jones on the, 292.
Farcy in man, 413.
Farquharson, Dr. Robert, notice of book by, 185.
Fecal fistula, 263.
Fees, old-time, 15.
Femur, reunited fracture of, treatment of by portative apparatus, 443.
Fibroid tumor of the uterus, hysterectomy for, 12; French views on the electrical treatment of, 547.
Field, Dr. Matthew D., a Chinese paretic, 660.
Fish poison, prize for the investigation of, 578.
Fissure, vesico-rectal, 152.
Fistula fecal, 263.
Flat-foot, or pes valgus acquisitus, 10.
Flint, Dr. Austin, notice of book by, 492.
Fœtus, a young living, 125, 244; macerated, as a complication of labor, 40; typhoid bacillus in the, 343.
Fogarty, Joe, death of, 71.
Food in its relation to health, 498; treatment by, of insomnia, 373.
Foods, artificial, official investigation of, 291; of different people, 400.
Forest, Dr. W. E., intussusception and the use of injections, 371.
Fowler, Dr. George R., partial resection of the head of the first metatarsal bone for hallux valgus, 253.
Fractures of the base of the skull, 566, 580; of the base of the skull, hemorrhage in the middle ear in, 497; ununited, advance in the treatment of, 606.
France, depopulation of, 378.
Fraulina scorbilis in dysentery, 671.
Freckles, removal of, 336.
Fredigké, Dr. Charles C., vaginal tamponage, 313.
Frontal sinuses, empyema of, 24.

G

Galactocele testis, 518.
Gangrene following continued fever, 342.
Gangrene, symmetrical, 72.
Garbage, disposal of, at Milwaukee, 498.
Garter, the, and varicose veins, 633.
Gastralgia, a new form of, 545.
Gastric electrode, a new, 530.
Gastric mucous membrane, reproduction of, 604.
Gastritis, acute, after the administration of turpeth mineral, 190; diffuse phlegmonous, 406.
Gastro-intestinal disorders in infants, mechanical treatment of, 418.
Gastrotomy for a set of false teeth, 464.
General paresis, ocular symptoms in, 132; trephining for, 635.
German Congress of Internal Medicine, 158.
German measles, 376.
Germany, condition of the medical profession in, 185; medicine in, an American view of, 476.
Gibbons, Dr. Richard H., protection for railway travellers, 529.
Gibney, Dr. V. P., the mechanial treatment of drop-wrist and allied paralysis, with presentation of a case, 482, 495.
Gillette, Dr. A. A., hæmatemesis in typhoid fever, 707.
Giraffe, birth of a, 504.
Glanders, death of a Vienna physician from, 635; in man, 413.
Glaucoma, 74; chronic, operation for, 130.
Gleet and sexual asthenia, mechanical treatment of, 265.
Glycerine in dyspepsia, 104; in the treatment of ozæna, 336.
Glycerine-soap suppositories, 671.
Glycosuria and its associations, 585; as influenced by the condition of the pancreas, 586; injurious effects of milk-diet in, 586.
Goitre, cystic, 65; cystic, electrolytic treatment of, 22.
Golding, Dr. J. F., syrupus acidi hydriodici, 333.
Gonococci, staining of, 568.
Gonorrhœa in a boy five years of age, 588; some points in the treatment of, 180; transmission of, as an indictable offence, 404; treatment of, 65, 474.
Gonorrhœal rheumatism, treatment of, 448.
Gott, Dr. William A., case of compound triple dislocation of the left astragalus, with comminuted fracture—recovery with a useful foot, 246.
Gougenheim, Dr. A., notice of book by, 185.
Gout, dietetic treatment of, 183; nature and treatment of, 160; uric acid and, 211.
Green, Dr. Traill, banquet to, 44.
Green soap in caries, 644.
Greene, Dr. J. L., pneumonia treated with peroxide of hydrogen, 66.
Griffin, Dr. E. Harrison, a peculiar case of tertiary syphilis of the throat, 289.
Grissom, Dr. E., acquitted, 129.
Grove, Dr. B. F., the Johns Hopkins Hospital and the dispensary abuse in Baltimore, 587.
Gruening, Dr. E., how is this? 643.
Guide to the practical examination of urine, book notice, 188.
Guide to therapeutics and materia medica, book notice, 185.
Gummata, miliary, in various organs in a young child, 163.
Gunshot wounds of the abdomen, 493.
Gynaia, a new disease, 464.
Gynecological work, report of, 609.
Gynecology and obstetrics, conservatism in, 676, 694; electricity in, 328, 334, 401; in its relation to obstetrics, 611; recent advances in, 408.
Gypsies, a good word for the, 154.

H

Habershon, Dr., death of, 291.
Hæmoptyses, the non-tubercular and non-cardiac, of elderly persons, 708.
Hair-balls in the stomach, 189.
Hairs, removal of by electrolysis, 84; removal of, by electrolysis, a new needle-holder for, 529.
Hallux valgus, partial resection of the head of the first metatarsal bone for, 253.
Hanchett, Dr. Mary E., death of, 184.
Handbook for the hospital corps of the United States army and State military forces, book notice, 186.
Handbook of general pathology, book notice, 491.
Handbook of skin diseases, book notice, 215.
Handbook of therapeutics, book notice, 492.
Hanging, some personal experiments with, 291.
Hare, Dr. Hobard Amory, notice of book by, 216.
Harris, Dr. Vincent Dormer, notice of book by, 216.
Hart, Dr. B. F., "both right and both wrong," 526.
Harveian oration for 1889, 525.
Harvey, Dr. Thomas B., death of, 687.
Hawes, Dr. John B., viper-bite treated by alcohol, 318.
Hay, Dr. C. M., a case of tricuspid stenosis associated with aortic and mitral lesions, 256.
Head, Dr. G. P., can naso-pharyngeal catarrh be cured? 82.
Head, treatment of injuries to the, 141.
Headache, antifebrin in the treatment of, 430; eucalyptol in, 104.
Health, height and weight in their relation to, 634; medical officers of, 272.
Health Department and the conference committee of the Academy of Medicine, 691.
Health-resort, a summer, 120, 212.
Heart, and kidneys, relations of lesions of, 355; congenital malformation of the, 416; first sound of the, 432; insufficiency of, in relation to abortion, 328; lesions and malformations of, 247; massage of, 435; movable, 343; spontaneous rupture of the, 447; therapeutics of the, 701.
Heart disease, iodide of potassium in, 662; Nothnagel on the treatment of, 606.
Heart-failure as a cause of death, 71; pathology of, 587.
Heart tonics, recent studies of, 279.
Heat, effects of, on the system, 670.
Height and weight in their relation to health, 634.
Hematemesis, arrest of, 319.
Hemoglobinuria, mode of, origin of, 317.
Hemoptysis, inhalations of cold air in, 559; non-tubercular and non-cardiac, of elderly persons, 525.
Hemorrhage, concealed ante-partum, 328; in typhoid fever, 660; intestinal, 554; uterine, ligation of the uterine vessels for, 284.
Hemorrhoids, chrysarobin in, 521; excision of, and closure with the buried animal suture, 389; pathogeny of, 670.
Henry, Dr. Morris H., the opportunity of relief for the poor of New York suffering from diseases of the rectum, 643.
Heredity, 314, 476; in infectious diseases, 602; influence of, in the causation of tuberculosis of bone, 550; of acquired characters, 584; pathological bearings of, 419.
Hernia, diaphragmatic, 417; double femoral, in a boy, 579; radical cure of, 73; strangulated, 495; strangulated, mistaken for uræmia, 13; strangulated, treatment of, 472; treatment of, 388, 505.
Hernial sac, malignant tumor in, 394.
Herniotomy, direct, 609.
Herpes zoster, 469; epidemics of, 102.
Hiccough, a simple remedy for, 364.
Hip, congenital dislocation of, 332, 441, 537.
Hip disease, abscesses in, 441; immediate disregard of malposition of the thigh in the treatment of, 440; prevention of the short leg of, 440; some practical points in the treatment of, 411; treatment of, 361, 441.
Hip-joint, amputation of, application of an artificial leg after, 391.
Hitchcock, Dr. DeWitt, a lost drainage-tube, 543.
Hoarseness, relief of, 420.
Hobbs, Dr. A. G., catarrhal neuralgia, 629.
Homœopathic Hospital, trouble at the, 685.
Homœopathy, the true status of, 15.
Hopkins, Dr. Howard H., snake-bite and alcohol, 431.
Hosack Hall, 380.
Hospital, an aërial, 290.
Hospitals, half-filled, 43; inquiry concerning, in London, 222.
Hotels, infectious diseases in, 273.
Humerus, subcoracoid dislocation of, reduced by Kocher's method, 13.
Hunter, Dr. James B., resolutions on the death of, 28, 488.
Hunyadi Janos, the owner of, 283.
Hydrargyrism, fatal acute, 586.
Hydrarthrosis of the knee, treatment of, 602; treatment of, by subcutaneous rupture, 267.
Hydriodic acid, syrup of, 333.
Hydroa, 277.
Hydrocele, nitrate of silver in, 363.
Hydrogen peroxide in pneumonia, 66; medicinal use of, 321: some cases treated with, 481.
Hydrophobia, prevention of, by Pasteur's method, 357.

Hydrotherapy, plea for the practical utilization of, 665; versus hydropathy, 686.
Hygiene, thermometry of, 639.
Hyperostosis cranii, 106.
Hypnotic cases without suggestion, 584.
Hypnotics, influence of, on the process of digestion, 155; new, 390.
Hypnotism, international congress of, 292; prolonged, in hysterical dysphagia, 82; some remarks on, 488.
Hypodermic method, an improved way of using the, 398.
Hypohæmatosis, 664.
Hysterectomy for large fibromyoma, 12; for œdematous myoma, 515.
Hysteria, grave case of, 82; pilocarpine in, 139.
Hysterical fever, 151.

I

Ichthyol, thiol as a substitute for, 280, 372.
Ileus, 158.
Imagination, hygienic uses of the, 270.
Immunity and immunization, 544.
Immunity through leucomaines, 186.
Impetigo herpetiformis, 502.
Inches, Dr. Herman B., death of, 244.
Index catalogue of the library of the Surgeon-General's office, U. S. A., book notice, 490.
Indians, disease-ridden, 558.
Indigestion, rubber bandages in, 403.
Infant, scorbutus in an, 305.
Infantile diarrhœa, vaccine for, 604.
Infantile mortality, causes of, 500; causes and prevention of, 466.
Infantile paralysis, orthopedics of, 473.
Infantile therapeutics, 472.
Infants, acute arthritis of, 443; entero-colitis in, 35; rheumatism in, 53.
Infection, by physicians, 548; physiological resistance of the peritoneum to, 545; some external sources of, in their bearing on preventive medicine, 85.
Infectious disease, compulsory notification of, 434, 661.
Infectious doctors, the notification of, 709.
Influenza, epidemic, 661; epidemic of, in Russia, 635, 710.
Ingenuity, misapplied, 340.
Ingrowing nail, treatment of with tin-foil, 632.
Inhaler, a simple, 532; anæsthetic, 669.
Injury, trivial, severe symptoms from, 66.
Inoculation, antirabic, new method of, 664; preventive, and the theory of its action, 182; preventive, for yellow fever, 699.
Insane in foreign countries, book notice, 492; our State, 633,
Insanity, alcoholism, and crime, 321; and tobacco, 400; following mumps, 461; the shadow line of, 388.
Insolation, successful treatment of, 287.
Insomnia, food treatment for, 373.
Insufficiencies, muscular, of the eye, outline tests for, 413.
Internal ear deafness, 23.
Internal strangulation, 190.
International Congress of Dermatology and Syphilography, 275, 301.
International pocket medical formulary: with an appendix containing posological table, formulæ, etc., book notice, 217.
Interviewer in the guise of a patient, 487.
Intestinal absorption, imperfect, and its management, 549.
Intestinal anastomosis, an experimental study of, 612.
Intestinal anastomotic operations with segmented rubber rings, 613.
Intestinal hemorrhage, 554.
Intestinal obstruction, 158; gaseous enemata for, 278; overcome by the passage of a rectal tube, 180; treatment of, by electricity, 222.
Intestinal surgery, book notice, 218.
Intestines, gunshot wounds of the, 493; large wounds of, a new procedure for closing, 613; pigmentation of, 190; syphilis of the, 484; tuberculosis of, 189.
Intra-cranial hemorrhage in a young child, 191.
Intranasal pressure, chronic lymphatic œdema of the upper lip coincident with, 63.
Intra-pelvic inflammations, pathology and treatment of, 511.
Intra-tympanic muscles, physiology of, 136.
Intubation of the larynx, early indications for, 25; feeding after, 312; for the removal of foreign bodies, 391; in cases of foreign bodies in the air-passages, 311; unusual case of, 97.
Intussusception and the use of injections, 371; coal-oil in, 336.
Iodide of potassium in heart disease, 662.
Iodides, alleged tolerance of, in late syphilis, 502.
Iodides of potassium and sodium, relative action of, 503.
Iodine in the treatment of warts, 448; poisoning by the tincture of, 98.
Iodoform-oil, parenchymatous injections of, in joint diseases, 575.
Iridectomy in glaucoma, 130.
Iris, multiple cysts of, 132.
Iritis, primary, diagnosis and treatment of, 411.
Irregular practitioners, association of, in Massachusetts, 663.
Isabella Heimath Retreat, 663.
Isolation, necessity of, 273.

Silk thread, danger in, 432.
Silver salts, germicidal value of, 114.
Sinners, breeding of, 364.
Sinus, longitudinal, ligature of the, 569, 580.
Sister Thérèse, a nursing heroine, 664.
Skin diseases, new remedies for, 98; of infancy and early life, book notice, 188.
Skin, malignant tumors of the, 470; unusual eruptions of, 116.
Skull, fractures of the base of the, 566, 580; fracture of the base, hemorrhage in the middle ear in, 497.
Sleeping, eating before, 529.
Small-pox, antiseptic treatment of, 576; illustration of, 486; salicylic acid in, 67.
Smart, Dr. Charles, notice of book by, 186.
Smith, Dr. Andrew H., saccharin as a means of acidifying the urine, 541, 553.
Smith, Dr. Howard, observations at the clinic of Dr. Apostoli in Paris, 138.
Smith, Dr. J. Lewis, Jr., death of, 71.
Smith, Dr. J. R. N., late pregnancies, 399.
Snake-bite and alcohol, 318, 431.
Snoring, cure for, 16.
Snow, Dr. Irving M., the etiology of rickets, 278.
Snowden, Dr. Thomas, death of, 435.
Soap as an antidote to carbolic acid, 577.
Socialism, relation of medicine to the problem of, 673.
Society fever versus yellow fever, 193.
Somnol, a new hypnotic, 551.
Sordes and thrush, remedy for, 488.
South Alberta, climate of, 361.
Southern Surgical and Gynecological Association, 609, 637.
Spain, proposed medical congress in, 489.
Spectacles, colored, 480.
Speculum, mastoid retracting, 643; nasal, for applying caustics to the deep structures, 250.
Spermine, 484.
Spinal column, relation of the thoracic and abdominal walls to the, 440.
Spinal cord, degenerative diseases of the, caused by malaria, 105; suspension in the treatment of affections of the, 472.
Spine, lateral curvature of, new exercise in the treatment of, 443; operations on, for pressure paralysis, 444; surgery of, 20; the typhoid, 440.
Spleen, insertion of, into the abdomen, 378.
Splenic murmurs, 67.
Spondylitis, when may treatment be dispensed with? 443.
Sprains, treatment of, 551.
Spray, cooling the body by, 699.
Squire, Dr. Truman H., death of, 710.
Stable refuse, disposition of, 663.
Stark, Dr. Henry S., a new pocket-case, 195.
State examinations for license to practice, 242, 642; Florida joins the procession, 709.
Statistics, vital and medical, 589, 617, 645, 684; vital, deficiencies of our, 43.
Stenosis, tricuspid, associated with aortic and mitral lesions, 256.
Sterility in woman, 473.
Stevens, Dr. George T., the prevention of sea-sickness, 527.
Stillman, Dr. Charles F., notice of book by, 217.
Stockton, Dr. Charles G., a new gastric electrode, 530.
Stomach, acids of the, 632; carcinoma of, œdema as a diagnostic sign in, 484; dilatation of, 159; dilatation of, in tertiary syphilis, 303; effects of acids on the functions of the, 374; elimination of morphine by the, 373; motor insufficiency of, diagnostic value of the salol test in, 636; multiple ulcers of, in an opium habituée, 221; reproduction of the mucous membrane of, 604; rest and cleanliness of the, 48.
Stomach-brush, 557.
Stools, colorless, in unjaundiced persons, 124.
Stout, Dr. Henry R., society fever versus yellow fever, 193.
Strabismometer, 167.
Strahan, Dr. John, notice of book by, 217.
Straughn, Dr. J. H., twins with one placenta, 461.
Stricture, urethral, electrolysis in, 83, 697.
Strophanthus as a local anæsthetic, 399.
Strophanthus, use of, in children, 603.
Strychnine in the alcohol habit, 255.
Study, Dr. Joseph N., high temperature in typhoid fever, 660.
Sublimate irrigation after abortion, death from, 517.
Sugar, detection of, by safranine, 333; of milk as a diuretic, 44, 377.
Suggestive therapeutics, book notice, 492.
Suicide, workings of the law against, 14.
Sulphonal, 362; death from, 185; dosage and effects of, 62; in night-sweats, 336; long sleep from, 560.
Sulphur dioxide, disinfection of dwellings by, 499, 533.
Summer diarrhœa of infancy, 417; bacteria found in the dejecta in, 418.
Summer health-resort, 120, 212.
Sunstroke, successful treatment of, 285.
Suppuration without microbes, 545.
Surgeon's responsibility and murderer's guilt, 211.
Surgery, a treatise on, book notice, 490; cocaine in, 566; detail in, 232.
Surgical bacteriology, book notice, 492.
Surgical cases, general management of the patient and sick-room in, 73.
Suspension in affections of the spinal cord, 472.
Suture button, a new form of, 400.
Sutures, choice of, in abdominal section and the Cæsarean operation, 319; knots and ligatures, 449, 494.
Sweating of the feet, chromic acid in, 100.
Sycosis, clinical notes on, 501; of the upper lip, treatment of, 501.
Synopsis of human anatomy, book notice, 490.
Syphilis, dilatation of the stomach in, 303; in old age, 347; injection of insoluble mercurial salts in, 471; laryngeal, 78; late, alleged tolerance of the iodides in, 502; of the intestines, 484; tertiary, 302, tertiary, of the throat, peculiar case of, 289; thymol-mercury in the treatment of, 575; transmission of, through surgical instruments, 586; treatment of, 302; tropho-neurosis as a factor in the phenomena of, 637; ways and wanderings of the contagion of, 67.
Syphiloma of the tongue, apparent cancerous transformation of, 456.

T

Tabes, pathology of the laryngeal and other crises in, 690.
Tachycardia, essential, 605.
Tæniacide, cocoanut as a, 400.
Tait, Mr. Lawson, a visit to, 148.
Tampon, use of the, in pregnancy, 285.
Tamponage, vaginal, 313.
Tansy, poisoning by, 342.
Tape-worm, male fern and calomel for, 372.
Tarbox, Dr. O. C., report of sixteen cases of typhoid fever, with remarks, 209.
Tauszky, Dr. Rudolf, death of, 608.
Taylor, Dr. Morse K., death of, 616.
Taylor, Professor Isaac E., obituary of, 490; resolutions on the death of, 520, 551.
Teale, Mr. T. Pridgin, detail in surgery, 232.
Teeth, and ears, relation between diseases of, 119; eruption of, in old age, 560.
Telegraphers, sensibility of, 335.
Tendon-sheaths, excision of tubercular bodies in, 494.
Tendons, divided, suture of, 493.
Terrillon, Dr. O., notice of book by, 492.
Testicular fluid, injection of, as a rejuvenator, 69, 70, 81, 128, 205, 210, 323.
Testis, congenital absence of right, and ectopia of left, 631; tuberculosis of the, in childhood, 416.
Tetanus, traumatic, 77.
Tetany, 349.
Texas fever in cattle, 468.
Text-book of human physiology, book notice, 492.
The life insurance examiner: a practical treatise upon medical examinations for life insurance, book notice, 217.
The old hospital and other papers, book notice, 216.
The student's text-book of practice of medicine, book notice, 216.
The year-book of treatment for 1889: being a critical review of the practice of medicine and surgery during 1888, book notice, 218.
Theophyllin, a new constituent of tea, 547.
Therapeutic work at the Paris exposition, 322.
Therapeutics, physiological, and chemical structure, 126.
Thermo-palpation, 672.
Thiol, a substitute for ichthyol, 280, 372.
Thomas, Dr. J. D., an improved urethrotome, 279.
Thompson, Dr. Austin White, death of, 71.
Thompson, Dr. James B., determination of sex, 333.
Thompson, Dr. W. Gilman, the therapeutic value of oxygen inhalation, with exhibition of animals under high pressure of oxygen, 1, 26.
Throat, tertiary syphilis of the, 289.
Thrombosis of the cerebral sinuses and veins, 350; of the middle cerebral artery, 666.
Thrush and sordes, remedy for, 488.
Thymol-mercury in the treatment of syphilis, 575.
Thyroid gland, accessary, at the base of the tongue, 16.
Thysotomy for the removal of a sarcoma, 26.
"Tip-cat," the danger of, 532.
Tissier, Dr. Paul, notice of book by, 185.
Titus, Dr. E. C., a few clinical cases showing the value of oxygen combined with nitrogen monoxide in the treatment of pulmonary and other troubles, 370.
Tobacco and insanity, 400.
Tobacco hysteria, 663.
Tonghinine, a new heart poison, 104.
Tongue, accessary thyroid gland at the base of, 16; apparent cancerous transformation of syphiloma of the, 456; fissures of, 265; tonsil of the, 22.
Tonsil, lingual, 22; so-called third, 24.
Tonsillitis, antifebrin in, 604; salicylic acid in, 339.
Torticollis, functional, 443.
Trachea, erosion of, from aneurism of the aorta, 304; movement of the, 586.
Trachoma, anterior, the curette in, 131.
Traité d'hystérotomie et d'hystérectomie par la voie vaginale, book notice, 492.
Transactions of the American Surgical Association, vol. ii., book notice, 491.
Transactions of the American Surgical Association, vol. vi., book notice, 216.
Transactions of the Association of American Physicians—third session—book notice, 490.
Transactions of the New York State Medical Association for the year 1888, book notice, 490.
Transactions of the Royal Academy of Medicine in Ireland, book notice, 216.
Transactions of the thirty-fifth Annual Session of the Medical Society of North Carolina for the year 1888, book notice, 215.
Transfusion, reciprocal, in typhoid fever, 269.
Trephining for actinomycosis of the brain, 333; for cerebral abscess, 317, 461; for general paralysis, 635; successful treatment of cerebral abscess by, 317; the lateral ventricle, 291.
Tricuspid stenosis associated with aortic and mitral lesions, 256.
Triplets with one placenta, 644.
Tri-State Medical Association, 588.
Tubal pregnancy, discussion on, 386.
Tubercle bacilli, mode of dissemination of, in the body, 657.

Tubercular peritonitis, surgical treatment of, 102, 517.

Tuberculous disease of the serous membranes, 294.
Tuberculous infection through earrings, 267.
Tuberculous pulmonary aneurism, 398.
Tumors, pathogenic properties of microbes found in, 576.
Tunica vaginalis, hypertrophy of, 219.
Turner, Dr. Edward J., death of, 157.
Turner, Dr. S. S., determination of sex, 528.
Turpentine, new eruption from, 545.
Turpeth mineral, acute gastritis following the administration of, 190.
Twins with one body, 209; with one placenta, 461.
Tympanic attic, inflammation of, 134.
Tympanites, posture in the treatment of, 265.
Typhlitis, relapsing, 330; surgical treatment of the, 330.
Typhoid bacillus in the fœtus, 343.
Typhoid fever, behavior of the germs of, in milk, butter, whey, and cheese, 483; cold-bath treatment of, in Australia, 348; colon-flushing in, 340; etiology and pathology of, 46; hæmatemesis in, 707; hemorrhage in, 660; high temperature in, 660; physiological action of the poison of, 704; one of the causes of, 627; reciprocal transfusion in, 269; report of sixteen cases of, 209.
Tyson, Dr. James, notice of book by, 188.

U

Udell, Dr. P. S., an improved way of using the hypodermic method, 398.
Ulexine, a new cardiac remedy, 546.
Umbilical cord, rational dressing and treatment of, 387.
Uræmia, strangulated hernia mistaken for, 13.
Uræmic convulsions controlled by morphine, 631.
Ureters, psorospermial cysts of, 99.
Urethra, dilatation of the male, for the removal of vesical calculi, 101; new operation on the, 671; stricture of, electrolysis in, 83, 697.
Urethrotome, an improved, 279.
Urethrotomy, dilating, an experience of seventeen years with, 57.
Uric acid and gout, 211; excretion of, and its relation to mental depression, 374; formation of, relation of diet to, 393, 405.
Urine, lead in the, 355; new test for albumin in, 664; of business men, 475; residual, symptomatic indication and therapy of, 546; retention of, from prostatic enlargement, treatment, 331; saccharin as a means of acidifying the, 541, 553.
Uterine apparatus, influence of morphine upon, 99.
Uterine appendages, a protest against the removal of the, 711.
Uterine injections, two-ways catheter for, 50.
Uterine system, asthma and the, 604.
Uterus, cancer of, treatment, 300; cancer of, with involvement of the ovaries, 164; epithelioma of, 556; erosions of the os, in monkeys, and their pathological relation to cancer in human females, 697; fibroid of, hysterectomy for, 12; hemorrhage from, ligation of the uterine vessels for, 284; partial inversion of, 385; puerperal, irrigation of, 265; rupture of, laparotomy and supravaginal amputation for, 478; tolerancy of the pregnant, 707; ultimate results of extirpation of the, 604.

V

Vaccination on the leg, 560; compulsory in the United States, 708.
Vagina, tamponage of, 313.
Van Dyke, Dr. F. W., antiseptics and the country doctor, 712.
Van Harlingen, Dr. Arthur, notice of book by, 215.
Varicocele, satyriasis caused by, 181.
Varicose veins, the garter and, 633.
"Vaso-motor centre itis," 578.
Veins, air in the, 345.
Venesection in puerperal eclampsia, 74.
Ventilation in Iceland, 336.
Ventricle, lateral, trephining the, 291.
Vermiform appendix, perforation of, 304.
Version, cephalic, eighteen hours after rupture of the membranes, 543.
Vertebral pain, a new form of gastralgia, 545.
Veterinary practice, regulation of, 70.
Vicany, Thomas, notice of book by, 215.
Viper-bite treated by alcohol, 318, 431.
Viscum flavescens, an oxytocic, 118.
Vital statistics, 589, 617, 645; deficiencies of our, 43.
Vitreous, vascular growth in, 132.
Vomiting of pregnancy, menthol in, 465.
Von Volkman, Professor Richard, obituary of, 636; as a poet and littérateur, 710.
Vulliet, Dr., notice of book by, 492.
Vulva, new growth of, a hitherto undescribed form of, 501.

W

Walker, Dr. Henry F., tubal pregnancy treated by faradic current, 539, 553.
Wallace, Dr. T. C., the internal use of chloroform, 82.
Warts, iodine in the treatment of, 448; local treatment of, 644; tincture of iron internally for, 181.
Washburn, Dr. W., eating before sleeping, 529.
Washington State Medical Society, organization of, 608.
Wasp-sting, fatal result of a, 547.
Water, relation of conduits to the healthfulness of, 639.
Water-supply of New York City, 403.
Waters, Dr., suicide of, 44.
